Abstract

The empirical literature on the asset allocation and medical expenditures of U.S. households consistently shows that risky portfolio shares are increasing in both wealth and health whereas health investment shares are decreasing in these same variables. Despite this evidence, most of the existing models treat financial and health-related choices separately. This paper bridges this gap by proposing a tractable framework for the joint determination of optimal consumption, portfolio and health investments. We solve for the optimal rules in closed form and show that the model can theoretically reproduce the empirical facts. Capitalizing on this closed-form solution, we perform a structural estimation of the model on HRS data. Our parameter estimates are reasonable and confirm the relevance of all the main characteristics of the model.

Keywords: Portfolio, Health Investment, Mortality Risk.

JEL Classification. G11, I12.
Introduction

Conventional wisdom suggests that how wealthy and healthy we are determines how we allocate resources between financial and health-related investments. The empirical literature on asset allocation and health investments confirms that this is indeed the case and has outlined three main regularities. First, risky portfolio shares are increasing in both wealth (e.g. Wachter and Yogo, 2008; Carroll, 2002) and health (Guiso et al., 1996; Rosen and Wu, 2004, among others). Second, health investment shares are decreasing in both wealth (e.g. Meer et al., 2003; DiMatteo, 2003) and health (e.g. Smith, 1999; Yogo, 2008). Third, labor income is increasing in health (e.g. Smith, 1999; Rosen and Wu, 2004), although the sensitivity to health tends to decline after retirement (Smith, 1999).

Such strong interactions indicate that the analysis of financial and health investments should be undertaken as that of a joint decision process. Yet, aside from rare exceptions (e.g. Edwards, 2008; Yogo, 2008), the two are almost always analyzed separately in theoretical frameworks. At the risk of over-simplifying, health investment models tend to abstract from financial investment decisions whereas health related considerations are usually absent from portfolio choice models.

The objective of this paper is to bridge this gap by proposing a tractable model of joint consumption, portfolio and health investment decisions. Our modeling strategy innovates by combining two well-accepted —but otherwise segmented —frameworks from the Financial and Health Economics literatures within a unified setup. More precisely, we start from a standard Merton (1971) asset allocation problem with IID returns and intermediate consumption utility, and append to this model a costly health investment decision à la Grossman (1972) where better health improves labor income as well as reduces the agent’s mortality risk through a decrease in his death intensity. We solve for the optimal rules in closed form and show that the model can theoretically generate portfolios that increase in health and wealth, along with health investment shares that decrease in these same variables. The closed-form theoretical predictions of the model are very tractable and allow us to estimate the key parameters of the model using data from the Health and Retirement Study (HRS). In particular, we find that
the model is able to fit the data with reasonable parameter estimates which confirm the relevance of all the model’s main characteristics.

As is well-known (e.g. Shepard and Zeckhauser, 1984; Rosen, 1988, among others), the choice of preferences is not innocuous in an endogenous mortality setting such as ours. This occurs because, in the presence of endogenous mortality, preferences are no longer invariant to monotone transformations. In the standard time-additive framework of Yaari (1965) and Hakansson (1969) utility is computed as a sum of discounted period utilities up to the random time of death. This associates death with a utility level of zero and, thus, implies that the utility of any consumptions schedule must be compared to zero in order to determine whether the agent is better off living or dying. In particular, power utility with a relative risk aversion coefficient larger than one, as is often the case in the literature, implies negative welfare levels and, thus, yields the counterintuitive result that death is preferable to life.\(^1\) Our approach to this problem innovates by resorting to recursive preferences which allow to measure utility and consumption in the same metric (Epstein and Zin, 1989; Duffie and Epstein, 1992). With such preferences death is associated with a consumption level of zero whereas life corresponds to strictly positive consumption and, since preferences are monotonic, it follows that life is always preferred to death, regardless of parameter values. A second important feature of our preference specification is non-homotheticity. Iso-elastic utility with IID returns and a constant investment set counterfactually imply that portfolio shares are invariant to wealth levels (Merton, 1971). Introducing subsistence consumption is a convenient way to generate decreasing relative risk aversion and thus risky portfolio shares that profactually increase in financial wealth (Ameriks and Zeldes, 2004; Carroll, 2002; Wachter and Yogo, 2008).

In our model, health investment is subject to diminishing returns to scale and enters the agent’s decision problem through two channels. First, better health increases labor income through, for example, less frequent sick leaves and/or better access to promotions

\(^1\)To avoid this outcome, proposed solutions include adding a sufficiently large positive constant to utility (see Rosen, 1988; Becker et al., 2005; Hall and Jones, 2007, among others) and restricting the relative risk aversion to be smaller than one (Shepard and Zeckhauser, 1984). Another possible solution is to equate death with full depreciation of the health stock and impose Inada conditions on the flow utility of health, see Yogo (2008).
for more assiduous workers. Second, better health lowers—but does not completely eliminate—mortality risk by reducing the agent’s death intensity. In order to gain some intuition on the respective impact of these two channels, we first abstract from the latter to focus on the former only. In this restricted case, the agent’s mortality risk is independent from his health status and this allows us to solve for the optimal rules in closed form. These optimal rules reveal that the risky portfolio shares are proportional to the ratio of total disposable wealth (i.e. financial wealth plus the net present value of labor income net of investment and subsistence) to financial wealth. Since total disposable wealth increases in the health level, it follows that the risky portfolio shares increase in health as well. They profactually increase in financial wealth as well for certain levels of health and wealth. We also find that the health investment level is proportional to the health level. Health investment shares thus profactually fall in financial wealth, but counterfactually increase as the agent’s health improves.

Allowing for a health-dependent death intensity makes the agent’s mortality risk endogenous and, unfortunately, implies that the model can no longer be solved in closed form. To circumvent this difficulty, we resort to a perturbation analysis which uses the explicit solution of the health independent mortality case as a benchmark for a first order expansion with respect to the parameter which governs the health dependence of the agent’s death intensity.\(^2\) While it only provides an approximation of the optimal rules, this perturbation method nevertheless presents several advantages. In particular, it gives us explicit expressions for the optimal rules and, thus, allows us to interpret the comparative statics of the model without relying on numerically calibrated parameters. We find that, up to a first order approximation, portfolio shares remain independent of mortality and, therefore, conclude that most of the impact of health on portfolios obtains through the labor income channel. By contrast, we find that endogenous mortality risk does have a first order impact on the optimal health investment. The comparative statics of the optimal investment depend on the agent’s characteristics but we show that, contrary to its exogenous mortality version, the model with endogenous mortality has the potential to reproduce the observed co-movements.

\(^2\)Examples of papers which apply similar perturbation methods in asset pricing include Kogan and Uppal (2002), Kogan (2001), Chan and Kogan (2002) and Ferretti and Trojani (2005) among others.
A second advantage of our solution method resides in econometric tractability. Indeed, an attractive characteristic of the first-order approximation is that the associated portfolio and health investment rules are conditionally linear in variables that can be constructed from the observed health and wealth levels. We capitalize on this feature to estimate the key parameters of our model from a cross-sectional perspective using data from the Health and Retirement Survey. This structural estimation allows us to verify several hypotheses about the main features of the model. First, we use the health dynamics parameters to test for exogenous depreciation of the health stock, whether or not health investments affect future health levels, and if these investments are subject to diminishing returns to scale. Our estimation results indicate that health depreciates rapidly in the absence of investment. While agents can adjust health, they face strongly diminishing returns in doing so. Second, the estimated parameters of the agent’s death intensity allow us to test for both health-dependent mortality and the presence of an incompressible mortality component. While a sizeable share of mortality risk is captured by the incompressible part, we find that agents can adjust their death intensity, and thus also their life expectancy, through health improving investments. Third, the estimated preference parameters allow us to test for non-homothetic recursive preferences. Our estimates confirm that the preferences are characterized by positive minimal subsistence level, moderate risk aversion and low elasticity of inter-temporal substitution. Therefore, the null hypothesis of homothetic preferences is rejected as well as that of time additive utility. Taken together, our estimation results underline the relevance of our modeling strategy by showing that the technological, distributional and preference features of our model are all key ingredients in order to explain the empirical regularities.

Perhaps the three most closely related papers are those of Edwards (2008), Yogo (2008) and Hall and Jones (2007). Edwards (2008) does allow for asset selection in the presence of health risks, but he completely abstracts from horizon uncertainty and health-dependent income. Moreover, his distributional assumptions on health are quite different from ours since, in his model, sickness is purely exogenous and requires constant expenditures once incurred. As a result, Edwards (2008) can neither address the joint
determination of portfolios and health investment as we do, nor study the impact of endogenous life expectancy on the agent’s decisions.

Yogo (2008) is closer to us in that he also considers portfolio implications of a model à la Grossman (1972) where health investments are subject to diminishing returns to scale. However, his focus on the welfare gains of actuarially fair annuities is quite different from ours. Moreover, he models health as generating direct utility flows instead of our health-dependent labor income approach. Finally, we estimate all the structural parameters of our model from the predicted rules instead of estimating the health transition probabilities, and then calibrating the remaining key parameters to solve the model numerically as he does.

Hall and Jones (2007) also consider an endogenous mortality model with costly health investment and positive service flows of better health. However, they do not consider portfolio allocations and their focus on the time series of aggregate health spending and longevity is very different. Our preference specification also differs as we advocate non expected utility to guarantee that life is valuable, instead of adding a positive constant to utility in order to raise the relative value of life. Finally, we propose a full econometric estimation of the whole model, whereas their two-step procedure estimates the parameters of the health production function before calibrating the preference parameters in order to solve the model numerically.

The rest of this paper is organized as follows. Following a discussion of the empirical properties of health and financial investments in Section 1, we outline the theoretical model in Section 2. The solution to the model is presented in Section 3. We then turn to the econometric model and estimation results in Section 4. Finally, a conclusion in Section 5 reviews the main findings and suggests potential research agenda.

1 Data

In order to motivate the construction of our model, we first look at the empirical facts that characterize the cross-section of risky asset and health investment shares for a subset of American households. In particular, we outline in this section how health, wealth and age affect risky asset and health investment shares as well as labor income.
Although we rely on summary statistics to describe the relevant co-movements, our conclusions are reasonably robust to reduced-form econometric evaluations with socio-economic covariates.\(^3\)

1.1 Data sources and details

In our analysis, we rely on the Health and Retirement Study (HRS) data set, a widely-used survey of American individuals aged 51 and over.\(^4\) Although not fully representative of the entire age distribution of US agents, the HRS data allows for useful comparisons with other health investment studies that also analyze the same data set. It provides socio-economic variables, alternative measures of health status and health-related expenditures, in addition to holdings of financial and non-financial assets. We focus on a cross-sectional perspective using the fifth wave of HRS (respondents in 2000), with our sample including both married and single, male and female agents.\(^5\)

Regarding the definition of risky portfolios, we follow Rosen and Wu (2004); Berkowitz and Qiu (2006), in using a four-item classification of financial assets into safe assets (checking and saving accounts, money market funds, CD’s, government savings bonds and T-bills), bonds (corporate, municipal and foreign bonds and bond funds), risky assets (stock and equity mutual funds) and retirement accounts (IRAs and Keoghs). The first three items are the result of deliberate economic decisions and represent direct asset holdings, whereas retirement funds capture more indirect portfolio choices. Consistent with similar applications in the empirical asset pricing literature, we define net financial wealth as the sum of safe, risky and bond holdings minus debts, and omit pension as well as social security funds. Risky portfolio shares are simply the percentage of net financial wealth held in risky assets.

\(^3\)Specifically, regressing portfolios or health investment on health and wealth levels, with gender, race, age, or education co-variates through Tobit estimators yields qualitatively similar results.

\(^4\)We use the RAND Center for the Study of Aging version of the HRS data files. This data set includes the cohort associated with the Study of Assets and Health Dynamics among the Oldest Old (AHEAD), the Children of the Depression (CODA), the War Babies and the initial HRS. See RAND Corporation (2008) for details. The summary statistics that we report are robust to alternative sampling weights including uniform weights, household weights, or the person-level analysis weights provided in the RAND HRS data set.

\(^5\)The summary statistics that we report below are robust to the choice of the wave in the HRS data. As pointed out by Yogo (2008) the fact that male and female, unmarried and married individuals maximize different objective functions could result in a source of heterogeneity. However, all of our results are robust to accounting for such effects.
We follow a large strand of the Health Economics literature in selecting the self-reported general health status to measure the health of agents in the dataset. This polytomous variable is categorized as poor, fair, good, very good, or excellent. Finally, the RAND HRS data reports the agents' total health expenditures and we will use this variables as our measure of health investment. It includes medical expenditures (doctor visits, outpatient surgery, hospital and nursing home, home health care, prescription drugs and special facilities), as well as out-of-pocket medical expenses (uninsured cost over the two previous years). The health investment share is the percentage of net financial wealth spent on total health expenditures.

Table 1 presents summary statistics of the key variables, including demographic characteristics, health-related measures and financial wealth holdings. We distinguish between younger (age less than 65) and older agents (age greater than or equal to 65) and associate the latter with retired individuals. The average age is 58 for non-retired and 75 for retired, with a negligible difference between married and unmarried individuals. Females make up roughly 60% of the total sample of 19,571 observations. This percentage varies however with the marital status and is larger for singles.

As can be seen from the second panel of Table 1 the self-reported health distribution is skewed towards good or better for younger agents, but displays a deterioration after age 65. The average health-related total expenditures increases from $10,615 to $15,862 for older agents. These expenditures are generally higher for singles. The cross-sectional distribution of medical, out-of-pocket, or total expenses is characterized by a long upper tail with much lower median values (French and Jones, 2004).

For those agents with positive financial wealth, we notice that almost all (85%) hold safe assets. These assets constitute by far the largest share of financial wealth

---

[Insert Table 1 about here]

---

6See Smith (1999); Deaton and Paxton (1998); Rosen and Wu (2004); Berkowitz and Qiu (2006); Love and Smith (2007); Yogo (2008) for examples. The validity of self-reported health has been discussed extensively. See discussions in Benítez-Silva and Ni (2008); Croze, and Kennedy (2002); Hurd and McGarry (1995). For robustness, we also considered other health-related measures, such as the self-reported health change or the number of diagnosed conditions with no qualitative effect on our results.

7Our results are robust to using the self-reported retirement status available in HRS instead of a definition based on age.
and increase in the post-retirement period from 57 to 65%. In comparison, only 9% hold corporate and government bonds corresponding to a meager 2% of financial wealth. Stock holdings are observed for roughly a third of individuals and represent 20% of wealth on average, with minor differences in the pre- and post-retirement periods. Finally, debt remains sizable for many agents and falls noticeably after retirement.

1.2 Relevant co-movements

Tables 2 (non-retired) and 3 (retired) categorize sample statistics in terms of increasing health levels and increasing financial wealth quintiles for the means of the net financial wealth, the probability of holding risky assets, the risky share and the median of the health investment shares. Overall, both tables convey the same messages.

First, consistent with similar findings by Michaud and van Soest (2008); Meer et al. (2003); Adams et al. (2003), we notice relatively minor variations in financial wealth as health changes. This can be interpreted as indicating that financial and human wealth are segmented measures. Put differently, contemporary health determines total wealth through its impact on human and not on financial wealth. Second, we notice that both the probability of holding risky assets and the risky asset shares increase sharply in financial wealth. Similar findings have been highlighted by Wachter and Yogo (2008); Guiso et al. (1996); Carroll (2002). Third, consistent with Guiso et al. (1996); Rosen and Wu (2004); Coile and Milligan (2006); Berkowitz and Qiu (2006); Goldman and Maestas (2005); Yogo (2008), there exists a positive correlation between health and risky asset holdings. As the health level improves, both the probability of holding risky assets and the risky asset shares increase, especially for intermediate health level. Fourth, the health investment shares decrease when either financial wealth increases or

---

8The interpretation of this figure may be misleading since almost all individuals in our sample have Social Security wealth, which can be perceived as a safe asset (Rosen and Wu, 2004).

9We select the median for the health investment share instead of the mean. Contrary to the risky probabilities and portfolio shares, the health investment share is not restricted to lie on the unit interval. As such, it is more sensitive to extreme measures.

10Kochar (2004) finds similar health-portfolio links in developing countries. See however Love and Smith (2007); Fan and Zhao (2009) for a more reserved interpretation which accounts for unobserved heterogeneity.
health improves. Similar findings are discussed in Meer et al. (2003); DiMatteo (2003) (decreasing in wealth) and in Smith (1999); Yogo (2008) (decreasing in health).

Table 4 next presents descriptive statistics in function of health and age when wealth is fixed at the third quintile.\textsuperscript{11} We notice that both the probability of risky asset holdings and their portfolio shares fall at retirement, whereas the health investment shares tend to increase. However, conditional upon a given health level, the statistics show that both the risky asset holdings and the health investment shares are relatively independent of age in the post-retirement phase. The latter presents a flat pattern in the first 20 years following retirement but tends to increase over 85, probably reflecting the explosion in medical expenditures in the last period of life. Age-independent risky portfolios can also be found using the HRS data reported in Coile and Milligan (2006) to construct a measure of financial wealth that is similar to ours. Wachter and Yogo (2008); Gomes and Michælides (2005); Ameriks and Zeldes (2004); Rosen and Wu (2004); Poterba (2001) also document flat age profiles for risky portfolios. The flat profile for health investment shares is also consistent with weak age effects in international comparisons in health care expenditure shares once proximity to death is taken into account (Zweifel et al., 2004; Gerdtham and Jönsson, 2000; Felder et al., 2000).

Finally, we are interested in measuring the impact of health on revenues. For this purpose, we regress total income on health in Table 5 in order to gauge its impact.\textsuperscript{12} Overall, regardless of the type of estimator and/or the set of explanatory variables, the regressions convey the same message: income depends positively on the health level and this effect is larger in the pre- than in the post-retirement phase. French (2005); Smith (1999); Deaton and Paxton (1998); Bodie et al. (1992) also document the positive relation between health and labor income using American data whereas Kochar (2004) provides further evidence of strong health effects on income in developing economies. It can be explained by lower absenteeism for healthier workers, with potential implications for promotion decisions. The positive post-retirement health gradient highlights the fact

\textsuperscript{11}The results are relatively insensitive to the choice of the wealth quintile level.

\textsuperscript{12}We measure total income as the sum of earnings (wages/salary), capital income, pensions or annuities, Social Security benefits as well as unemployment and other government transfers.
that certain elders may still find it convenient to continue working after 65. The lower health gradient and higher constant term after that age reflects the increased importance of pension and other non-wage income in the post-retirement phase.

[Insert Table 5 about here]

To summarize, the analysis of the HRS data set reveals the following empirical regularities: (i) the contemporary financial wealth is independent of contemporary health level, (ii) the labor income depends positively on the health level, with a stronger effect in the pre- than in the post-retirement phase, (iii) both the risky portfolio and the health investment shares are relatively insensitive to age in the post-retirement phase. We have also shown that (iv) the risky portfolio shares of financial wealth increase in both health and in financial wealth. Conversely, (v) the health investment shares of financial wealth decrease in both health and in financial wealth. In the next section, our theoretical model will be constructed by assuming the first three regularities and will aim at reproducing the last two findings.

2 The model

This section describes the health and income dynamics, the economic environment and the agent’s preferences over lifetime consumption plans in the presence of partially controllable mortality.

2.1 Health dynamics and survival

In the spirit of Grossman (1972), we model the agent’s health status as a locally deterministic process whose growth/decay rate is a function of current health investment and health status. More precisely, we assume that the agent’s health status evolves according to

\[ dH_t = \left( I_t^{\alpha} H_t^{1-\alpha} - \delta H_t \right) dt, \quad H_0 > 0, \]

for some constants \( \alpha \in (0, 1) \) and \( \delta \geq 0 \).

The above dynamics specify that the agent’s health status depreciates at a rate \( \delta \) and that gross health investment \( I^\alpha H^{1-\alpha} \) displays constant returns to scale. This last
assumption implies that the growth rate of the agent’s health status has decreasing returns in the investment to health ratio. Hence, a given health investment will have a larger impact on the growth rate of health when the agent is sick, than when he is healthy. The constraint that health investment cannot be negative is standard in the Health Economics literature. It reflects the irreversibility of health related expenditures and the fact that health is not a traded asset.

Following Ehrlich (2000); Ehrlich and Yin (2005) and Hall and Jones (2007) among others, we model the agent’s mortality as a partially endogenous Poisson process whose intensity depends on the agent’s health status. Specifically, we assume that the agent’s death intensity is given by

$$
\lim_{s \to 0} \frac{1}{s} P_t \left[ t < \tau \leq t + s \right] = \lambda(H_t) = \lambda_0 + \frac{\lambda_1}{H_t^\xi}
$$

for some nonnegative constants $\lambda_0$, $\lambda_1$ and $\xi$ where $\tau$ is the random duration of the agent’s lifetime or, equivalently, the agent’s age of death and $P_t(\cdot)$ is a conditional probability. The fact that the intensity function is decreasing in health ensures that the agent’s survival probability:

$$
P_0[\tau > t] = E_0 \left[ e^{-\int_0^t \lambda(H_s)ds} \right]
$$

is monotone increasing in the health status. As the agent’s health status improves, his death intensity decreases but it never falls below the level $\lambda_0$. Intuitively, an agent can increase his survival probability by investing in his health and still die from a sudden shock, such as an accident, that is completely unrelated to his current health status. Alternatively, this incompressible part of the intensity can be interpreted as an endowed death probability that is determined by natural and/or biological factors.

13Similar decreasing returns to health investments can be found in Ehrlich and Chuma (1990) and Ehrlich (2000); Ehrlich and Yin (2005). An equivalent interpretation of equation (1) is that the agent’s is endowed with a health production function that is linear in gross health investment $I_g = I^\alpha H^{1-\alpha}$ but faces convex health adjustment costs given by $I = I_g^{1/\alpha} H^{1-1/\alpha}$.

14See for example Grossman (1972); Ehrlich and Chuma (1990); Chang (1996); Picone et al. (1998); Ehrlich (2000); Edwards (2008); Hall and Jones (2007).

15Note that if the agent forgoes the possibility of health investment, then our specification of the intensity function conforms with Gompertz’ law according to which human mortality rates increase exponentially with age. See Wetterstrand (1981) and Leung (1994) among others for details.
The assumption of a (locally) deterministic health status follows a long tradition in Health Economics of abstracting from minor health shocks when studying optimal health investment in the presence of partially endogenous mortality.\footnote{See Grossman (1972); Ehrlich and Chuma (1990); Ehrlich (2000); Chang (2005) and Hall and Jones (2007) among others.} By imposing this assumption, we explicitly abstract from inconsequential health shocks, such as suffering from a headache or a cold, that are non-life threatening and/or have limited income implications and focus on those mortal shocks whose probability of occurrence can be partially controlled through health investments.

The specification of the survival probability in equation (3) is closely related to that proposed by Ehrlich (2000) or by Ehrlich and Yin (2005). However, we differ along two dimensions. First, we make the incompressible part of the death intensity constant, rather than age-varying.\footnote{This assumption can be relaxed by letting the incompressible part of the intensity be a function of the agent’s age. Our results still hold in this more general setup but we maintain the assumption that $\lambda_0$ is constant for simplicity.} Second, we let the endogenous part of the death intensity be a function of the current health status rather than of the agent’s health investment. This assumption implies that the agent cannot fully solve contemporaneous health-related problems by investing large amounts in times of need and, hence, reflects the path dependence of health-related decisions.

2.2 Income dynamics

To introduce life cycle considerations into the model, we identify time $t$ with the agent’s age and assume that, if alive, the agent is employed ($i = e$) up to some fixed age $T$ and retired thereafter ($i = r$).

The agent’s flow rate of income/pension per unit of time depends on his employment status and is defined by

$$ Y_t = Y(t, H_t) = 1_{(T > t)} Y_t^e + 1_{(T \leq t)} Y_t^r. $$

In this equation, the nonnegative processes $Y_t^i$ are related to the agent’s employment status and are given by

$$ Y_t^i = Y^i(H_t) = y^i + \beta^i H_t, $$
for some nonnegative constants \( y^e, y^r, \beta^e \) and \( \beta^r \) where the nonnegative process \( H \) represents the agent’s health status.\(^{18}\)

Since \( \beta^i \) is nonnegative, the above specification implies that the agent’s income increases with his health status. A natural interpretation is that employers offer higher wages to agents who are in better health and thus less subject to be absent from work. Equivalently, a healthier agent tends to miss less workdays and, hence, receives higher labor income. Since \( \beta^r \) can be different from zero, the income specification of (5) allows for health dependent post-retirement income. As explained in Section 1 this potential dependence is due to the fact that some agents continue working even after retirement. Consistent with the empirical evidence also presented in Section 1, we allow for differences in pre and post-retirement health elasticities of income. In particular, we assume a lower health sensitivity in post-retirement income (\( \beta^r < \beta^e \)).

### 2.3 Preferences

Starting with the seminal contributions of Yaari (1965) and Hakansson (1969), the standard way of specifying preferences in the presence of mortality risk has been to assume that the continuation utility, to an agent of age \( t \), of a lifetime consumption plan \( c \) is given by

\[
U_t = 1_{\{\tau > t\}} E_t \left[ \int_t^\tau e^{-\rho(s-t)} u(c_s) ds \right]
\]

for some subjective rate of time preference \( \rho \geq 0 \) and some concave period utility function \( u(\cdot) \) satisfying standard regularity conditions.\(^{19}\)

As pointed out by Shepard and Zeckhauser (1984) and Rosen (1988), the level of the period utility function has important implications in such a specification since adding a nonnegative constant to \( u(\cdot) \) raises the value that the agent places on longevity relative to consumption. Put differently, in the presence of an uncertain horizon, preferences are

---

\(^{18}\)The model can be generalized to allow for age varying, stochastic intercepts \( y^e \) and \( y^r \). We restrict our analysis to constant intercepts for the sake of simplicity and in order to focus on the effect of health on the agent’s portfolio, consumption and health investment decisions.

\(^{19}\)See for example Richard (1975); Shepard and Zeckhauser (1984); Rosen (1988); Ehrlich and Chuma (1990); Ehrlich (2000); Becker et al. (2005); Edwards (2008); Hall and Jones (2007) and Yogo (2008) among others.
not invariant to affine and more generally monotone, transformations as they are in the
standard setting where the horizon is fixed and non random. This anomaly is due to
the fact that equation (6) attributes a utility of zero to death and, hence, implies that
the utility of any consumption schedule must be compared to zero in order to determine
whether the agent is better off living or dying. In particular, if the period utility is
taken to be of the HARA type
\[ u(c) = \frac{(c - a)^{1-\gamma}}{1-\gamma}, \quad c \geq a, \] (7)
for some nonnegative constants \( a \) and \( \gamma \neq 1 \) then the agent’s preferences towards
mortality depend on whether the risk aversion parameter \( \gamma \) is smaller or larger than
unity. In the former case, the utility of any consumption is positive and it follows that
the agent always prefers life to death. On the contrary, if \( \gamma > 1 \) as is often found in
empirical studies then the utility of any consumption plan is negative and it follows that
the agent counterfactually prefers death to life irrespective of his current consumption
level.

To obtain sensible results, most of the authors who use the preference specification
in equation (6) restrict their study to nonnegative period utility functions for which any
life is always preferred to death. Following this approach, Rosen (1988); Becker et al.
(2005) and Hall and Jones (2007) among others specify a period utility of the form
\[ v(c) = b + u(c) \]
where the constant \( b \) is chosen in such a way as to guarantee that the function \( v(\cdot) \)
is nonnegative. Unfortunately, such a constant exists only if the utility function is
bounded from below and it follows that this approach cannot be used to accommodate
the case where the period utility function is given by equation (7) for some risk aversion
parameter \( \gamma \) greater than unity.

Motivated by the above discussion and in particular by the fact that the specification
in equation (6) cannot reconcile an empirically plausible level of risk aversion with
a sensible behavior towards mortality, we will forgo the time additive specification.
Instead we assume that the agent has recursive preferences of the type proposed by Kreps and Porteus (1979); Epstein and Zin (1989) and Weil (1989) in discrete time; and by Duffie and Epstein (1992); Schroder and Skiadas (1999) in continuous time. As we show below, when generalized to include a random horizon, such preferences allow to remedy the above deficiencies of time additive preferences while maintaining a tractable setup.

Let $U_t = U_t(c)$ denote for the continuation utility, to an agent of age $t$, of a consumption plan $c$. Introducing a random horizon into the Kreps–Porteus preference specification of Duffie and Epstein (1992), we assume that $U$ satisfies the recursive integral equation

\[ U_t = 1_{\tau > t} E_t \left[ \int_t^\tau \left( f(c_s, U_s) - \frac{\gamma}{2U_s} |\sigma_s(U)|^2 \right) ds \right] \]  

where $\sigma(U)$ measures the instantaneous volatility of the continuation utility,\(^{20}\) and $f(\cdot)$ is the intertemporal aggregator defined by

\[ f(c, v) = \frac{v \rho}{1 - 1/\varepsilon} \left[ \left( \frac{c-a}{v} \right)^{1-1/\varepsilon} - 1 \right]. \]  

In the above equation the nonnegative constants $\rho$, $a$, $\varepsilon$ and $\gamma$ represent, respectively, the agent’s subjective rate of time preferences, his subsistence consumption level, his elasticity of intertemporal substitution and his risk aversion over static gambles.\(^{21}\)

As pointed out by Duffie and Epstein (1992), the fact that the aggregator function $f(\cdot)$ is homogenous of degree one with respect to $(c-a, v)$ implies that the continuation utility is homogenous of degree one with respect to $(c-a)$ and it follows that the agent’s utility is measured in the same unit as excess consumption. In particular, the agent’s utility is always nonnegative and, since death is associated with zero utility, it follows that the agent sees his own mortality as detrimental irrespective of whether his risk aversion coefficient, $\gamma$, is smaller or larger than unity.

\(^{20}\)More precisely, $\sigma(U) = d(U, Z)_t/dt$ measures the instantaneous covariance of the continuation utility process with the Brownian motion driving market returns.

\(^{21}\)In the absence of mortality risk, our specification of the agent’s preferences boils down to time additive power utility under the usual parametric restriction that $\varepsilon = 1/\gamma$. 

15
The specification of the continuation utility in equation (8) captures non homothetic preferences for \( a \neq 0 \) and iso-elastic preferences otherwise. Non homotheticity is often advocated as a mean to generate risky portfolio shares that increase in wealth.\(^{22}\) In the context of our model, non homotheticity arises at the optimum even if \( a = 0 \) since the presence of health dependent income and mortality implies that the agent’s indirect utility is non separable in financial wealth and health. However and as we explain in Section 3.1, having \( a > 0 \) remains necessary for the model to generate portfolio shares that increase in wealth.

Our specification of the agent’s continuation utility does not include bequest motives. The reason for this restriction is mainly technical: adding a bequest to our setup with endogenous mortality considerably complicates the analysis and prevents us from deriving closed form solutions even in the case where the death intensity is independent from the health status.\(^{23}\)

2.4 Financial market and budget constraint

The financial market is frictionless and consists of two continuously traded securities. The first of these securities is a locally riskless bond whose time \( t \) price is given by

\[
S_t^0 = e^{rt}
\]

for some constant rate of interest \( r > 0 \). The second security is a risky stock and we assume that its price evolves according to

\[
dS_t = \mu S_t dt + \sigma S_t dZ_t, \quad S_0 > 0,
\]

\(^{22}\)For example, Ait-Sahalia et al. (2004) and Wachter and Yogo (2008) assume that agents have non separable preferences in consumption and luxury goods. Campbell and Cochrane (1999) extend non separability to consumption and a habit stock, whereas Carroll (2002) adds a HARA bequest to a CRRA period utility function.

\(^{23}\)Although potentially relevant in an endogenous mortality setting, panel data evidence suggests that the role of bequest motives in explaining the behavior of retired agents is rather limited. For example, Hurd (2002) finds no clear evidence of a bequest motive behind savings decisions, whereas Hurd (1987) finds no differences in the saving behavior of the elderly who have children compared to those who don’t. Similarly, Hurd (1989) finds no significant difference in the net present value of expected bequests of elderly agents when there is a bequest motive compared to when there is none. Hurd and Smith (2002) document that the importance of post-retirement dis-saving implies low bequests.
for some constant growth rate $\mu \geq r$ and constant volatility $\sigma > 0$ where the process $Z$ is a one dimensional standard Brownian motion.\textsuperscript{24}

Let $w$ denote the agent’s financial wealth at birth and $\pi$ denote the fraction of his wealth that the agent invests in the stock. Under the usual self-financing requirement the agent’s financial wealth evolves according to

$$dW_t = (rW_t + Y_t - I_t - c_t)dt + W_t\pi_t\sigma(dZ_t + \theta dt),$$

subject to $W_0 = w$ where the constant $\theta = (\mu - r)/\sigma$ denotes the market price of risk induced by the prices of the traded assets.

### 2.5 The decision problem

In the first part of his life the agent is employed and has an horizon which is the minimum of $\tau$ and $T$. This implies that, prior to retirement, the indirect utility function and the optimal rules are functions of the agent’s age, $t$, financial wealth, $W$ and health status, $H$. In contrast, the indirect utility and optimal rules become age independent after retirement since our model does not distinguish age among retired agents. Taking this into account, we will from now on write all quantities as functions of $(t, W, H)$ with the understanding that the age dependence terminates after retirement.

The agent’s problem consists in choosing a portfolio, consumption and health investment strategy to maximize his lifetime utility. This implies that the indirect utility of the agent at age $t$ is given by

$$V(t, W_t, H_t) = \sup_{(\pi, c, I)} U_t(c),$$

subject to equations (1), (2), (4) and (12), where $U(c)$ is the continuation utility associated with the consumption plan $c$ through equation (8).

\textsuperscript{24}The assumption of a single risky security is made purely for expositional simplicity. Under the assumption of a constant investment opportunity set, the model can be easily generalized to include multiple risky securities.
Our formulation of the agent’s decision problem parallels the widely used approach of specifying a health dependent utility and omitting health dependent income.\(^{25}\) To see this, abstract from the dependence of the agent’s income on his employment status by letting \(y' = y, \beta' = \beta\) in equation (5) and set \(x = c - \beta H\). Straightforward manipulations reveal that

\[
V(t, W_t, H_t) = \sup_{(\pi, x, I)} U_t(x + \beta H),
\]

subject to equation (1) and the modified budget constraint

\[
dW_t = (rW_t + y - I_t - x_t)dt + W_t\pi_t\sigma(dZ_t + \theta dt).
\]

Hence, solving the agent’s optimization problem using the non separable, health dependent intertemporal aggregator

\[
g(c, H, v) = f(c + \beta H, v),
\]

and abstracting from health dependent income is equivalent to solving our formulation of the agent’s problem with health independent preferences and health dependent income.\(^{26}\)

Since the uncertain duration of his lifetime cannot be hedged by trading in the market, the agent faces an incomplete market. However, under the assumption of Poisson mortality, the agent’s problem can be conveniently transformed into an equivalent infinite horizon problem with endogenous discounting and complete financial markets. Indeed, using equation (3) and the law of iterated expectations we can write continuation utility as

\[
U_t(c) = 1_{\{\tau > t\}} U_t^o
\]

\(^{26}\)Relaxing the employment status restrictions \(y' = y, \beta' = \beta\) implies that the agent has an age and health dependent intertemporal aggregator whose health elasticity depends on the agent’s age/employment status through the constants \(\beta^e\) and \(\beta^r\).
where the process $U^o = U^o(c)$ satisfies the infinite horizon, recursive integral equation given by

$$U^o_t = E_t \left[ \int_t^\infty e^{-\int_t^s \lambda(H_u) du} \left( f(c_s, U^o_s) - \frac{\gamma}{2U^o_s} |\sigma_s(U^o)|^2 \right) ds \right]. \quad (14)$$

This formulation brings to light the two channels through which health enters the agent’s problem. First, health can be interpreted as a durable good which generates service flows through the agent’s income. Second, health determines the endogenous rate at which the agent discounts future consumption and continuation utilities. We show in the next sections that both channels are necessary to generate the observed patterns of portfolio and health investment shares.

3 Optimal rules

This section derives the solution to our model. As explained above, health enters the agent’s problem through two channels: the mortality channel and the income channel. In order to gain some intuition on the respective impact of these two channels we start by analyzing the case where the agent’s mortality is independent from his health status and, thus, cannot be controlled. We then turn to the analysis of the general case where the agent’s health status influences both his mortality rate and his income.

3.1 Health independent mortality

When $\lambda_1 = 0$ the agent’s mortality rate is constant and, as a result, his objective function is independent from his health. In conjunction with the fact that financial markets are complete, this implies that the problem can be solved in two steps as in the human capital model of Bodie et al. (1992). First, compute the optimal health investment by maximizing the present value of the agent’s disposable income. Second, obtain the optimal portfolio and optimal consumption plan by solving the problem of an hypothetical agent who has no income and no subsistence consumption, but whose financial wealth is equal to the total disposable wealth of the original agent.
Since financial markets are complete, the present value of the agent’s disposable income is given by

$$P(t, H_t) = \sup_{I \geq 0} E_t \left[ \int_t^{\infty} \xi_{t,s} (Y(s, H_s) - a - I_s) ds \right]$$

subject to equation (1), where the nonnegative process

$$\xi_t = \exp \left( -rt - \theta Z_t - \frac{1}{2} \theta^2 t \right)$$

is the stochastic discount factor induced by the price of the traded securities and we have set $\xi_{t,s} \equiv \xi_s / \xi_t$. The following proposition derives an analytical solution for the present value of the agent’s disposable income and for the optimal health investment.

**Proposition 1** Let $\lambda_1 = 0$ and assume that

$$\beta^r < (r + \delta)^{\frac{1}{\alpha}}.$$  

(17)

Then the present value of the agent’s disposable income and the optimal health investment strategy are given by

$$P(t, H) = B(t) H + C(t),$$  

(18)

$$I_0(t, H) = H \left( \alpha P_H(t, H) \right)^{\frac{1}{1-\alpha}} = H \left( \alpha B(t) \right)^{\frac{1}{1-\alpha}},$$  

(19)

where a subscript denotes a partial derivative,

$$C(t) = \int_t^{\infty} e^{-r(s-t)} (Y(s, 0) - a) ds,$$

(20)

and $B(\cdot)$ is a nonnegative function of the agent’s age which is defined in the appendix.

The restriction imposed by equation (17) is a transversality condition which guarantees that the present value of the agent’s disposable income is finite. Since the constants $r, \delta, \beta^r$ and $\alpha$ are all nonnegative by assumption, this restriction effectively limits the convexity of the agent’s health adjustment technology and/or sets a minimal health
depreciation rate to compensate for the sensitivity of the agent’s income to his health status.

The present value of the agent’s disposable income can be decomposed in two parts. First \( C(\cdot) \) gives the present value of the health independent part of the agent’s lifetime income net of subsistence consumption expenditures. Second, the product \( B(\cdot)H \) gives the present value of the health dependent part of the agent’s lifetime income net of optimal health investments, i.e. \( B(\cdot) \) measures the shadow price (i.e. marginal \( q \)) of health. The fact that both this present value and the optimal investment are linear in the agent’s health status follows from the linearity of the agent’s income and the Cobb-Douglas specification of the health adjustment technology.\(^{27}\)

Having computed the present value of the agent’s disposable income and the optimal health investment strategy, we now turn to the determination of the optimal portfolio and consumption strategy. Let

\[
N_t = N(t, W_t, H_t) = W_t + P(t, H_t)
\]

(21)
denote the agent’s total wealth net of subsistence consumption expenditures. Using the result of Proposition 1 in conjunction with equation (12) we obtain that the agent’s total disposable wealth evolves according to

\[
dN_t = (rN_t - x_t)dt + N_t \nu_t \sigma(dZ_t + \theta dt),
\]

(22)
where the modified portfolio and consumption strategy \((\nu, x)\) is related to the original one through \( \nu = (W/N)\pi \) and \( x = c - a \). This implies that the agent’s indirect utility function can be written as

\[
V_0(t, W, H) = F(t, N(t, W, H))
\]

(23)

\(^{27}\)See Uzawa (1969), Hayashi (1982) and Abel and Eberly (1994) among others for similar results in the investment literature where this property is referred to as the equivalence between marginal and average \( q \).
where the function $F(\cdot)$ is defined by

$$F(t, N_t) = \sup_{(x, \nu)} U_t(x + a)$$

subject to the dynamic budget constraint in equation (22). The solution to this modified portfolio and consumption choice problem with recursive utility and IID returns is well-known and can be found in Svensson (1989) and Obstfeld (1994) among others. Using this solution to construct the agent’s optimal strategy gives the following theorem.

**Theorem 1** Let $\lambda_1 = 0$ and assume that equation (17) and

$$A = \varepsilon \rho + (1 - \varepsilon) \left( r - \lambda_0 + \frac{1}{2} \theta^2 \right) > \left( r - \lambda_0 + \frac{1}{\gamma} \theta^2 \right)^+$$

hold. The indirect utility function of a living agent of age $t$ is

$$V_0(t, W, H) = \rho \left( \frac{A}{\rho} \right)^{1/\gamma} N(t, W, H),$$

and generates the optimal portfolio, optimal consumption and optimal health investment strategy given by

$$\pi_0(t, W, H) = \frac{\theta}{\gamma \sigma W} N(t, W, H),$$

$$c_0(t, W, H) = a + AN(t, W, H),$$

and equation (19). Here, $N(\cdot)$ represents the agent’s total disposable wealth as defined by equation (21) and $B(\cdot)$ is defined as in Proposition 1.

As explained in Smith (1996), the restriction imposed by equation (25) serves two purposes. On the one hand, it guarantees that the agent’s marginal propensity to consume, $A$, is strictly positive and, hence, that the optimal consumption plan $c_0$ is feasible. On the other hand, it insures that the indirect utility indeed coincides with the continuation utility of the optimal consumption plan $c_0$ as defined by equation (8) and, thus, is a transversality condition. The exact form of the restriction is entirely
standard (e.g. Svensson, 1989; Smith, 1996), except for the presence of the mortality rate $\lambda_0$ which reflects the impact of mortality on the agent’s consumption decisions.

It is of interest to contrast the optimal rules in Theorem 1 with those obtained under separable VNM utility. To do so, assume that $\varepsilon = 1/\gamma$ so that, absent mortality risk, the agent has time additive preferences. In this case equation (25) gives

$$A^\nu = A|_{\varepsilon=1/\gamma} = \frac{\rho + \lambda_0}{\gamma} + \left(1 - \frac{1}{\gamma}\right) \left(r + \frac{1}{2\gamma} \theta^2\right) - \lambda_0$$

which is different from the marginal propensity to consume $A^{\nu \text{nm}} = A^\nu + \lambda_0$ that would be obtained under the time additive HARA preference specification of equations (6) and (7). The reason for this difference is that we take into account the impact of mortality on the certainty equivalent of future consumption and not on its utility. This allows us to guarantee that mortality is detrimental to the agent.

Equation (25) reveals that introducing exogenous mortality is equivalent to decreasing the interest rate and thereby leads to two conflicting effects. First, a lower interest rate implies that more resources are needed to fund a given amount of future consumption and, thus, encourages the agent to consume less today in order to maintain the same level of future consumption. Second, a decrease in the interest rate implies that current consumption is less costly relative to future consumption and, thus, leads to consume more today through a substitution effect. When the elasticity of intertemporal substitution, $\varepsilon$, is smaller than unity, the first effect dominates and the agent reduces his marginal propensity to consume in response to exogenous mortality. Conversely, when the elasticity of intertemporal substitution is greater than unity, the substitution effect dominates and the agent increases his marginal propensity to consume in response to an increase in his mortality rate. Exact cancelation of the two effects occurs if $\varepsilon = 1$ in which case mortality has no impact on consumption.

Equations (26) and (27) show that, when the agent cannot control it, mortality risk decreases his indirect utility function but has no impact on the optimal portfolio. The intuition behind these results is straightforward. Indeed, an increase in the mortality rate implies a decrease in the utility of any given consumption schedule and, hence, a decrease in the indirect utility. On the other hand, the property that the optimal
portfolio is independent from the agent’s mortality rate follows from the well-known fact that, in the absence of hedging demands, the optimal portfolio is independent of the agent’s planning horizon, (see Richard, 1975, for details).

The share of the agent’s wealth allocated to risky assets has the usual mean variance efficient form in that it is increasing in the market Sharpe ratio, $\theta/\sigma$ and decreasing in the risk aversion parameter, $\gamma$. However and in stark contrast to the standard case of homothetic preferences without human capital ($a = \beta^i = y^i = 0$), the optimal portfolio share is not constant but a function of the agent’s age, wealth and health status. As the agent’s health improves, the present value of his disposable income increases and his portfolio share increases.\(^{28}\) To understand this effect it suffices to observe that the presence of income and a non zero subsistence consumption level generates an endogenous liquidity constraint which forces the agent to keep his financial wealth, $W$, high enough for his total disposable wealth, $N$, to be nonnegative. As the agent’s health status improves, this constraint softens due to the increase in the present value of future income and, consequently, more risky assets can be held today.

The impact of the agent’s financial wealth on his portfolio share depends crucially on whether the present value of his disposable income is positive or negative. Since the agent’s health is deterministic along the optimal path, the present value of his disposable income is also non stochastic. In the spirit of Bodie et al. (1992), this implies that receiving this disposable income is equivalent to holding a position in the bond. When the present value of his disposable income is positive (negative), the agent implicitly holds a long (short) position in the bond and thus can invest more (less) in the risky asset than he would have absent human capital. As the agent’s financial wealth increases, the absolute value of this implicit position in the bond decreases in percentage of financial wealth and, as a result, his portfolio share gets closer to the constant share $\theta/(\sigma\gamma)$ that he would have chosen in the absence of human capital and subsistence consumption. This implies that the agent’s portfolio share increases as a

\(^{28}\)Throughout this discussion we maintain the assumption that the agent’s financial wealth is nonnegative. If this is not the case then the comparative statics of the optimal portfolio share with respect to financial wealth and health status are simply reversed due the mechanical effect of dividing by a negative quantity.
function of wealth as long as the present value of his disposable income is negative and
decreases otherwise.

In order for the present value of the agent’s disposable income to be negative, as
required to generate the observed patterns of portfolio shares, it must be the case that
(i) his subsistence consumption level is high enough relative to the health independent
part of his labor income in the sense that $C(t) \leq 0$ and (ii) that his health status is not
too high. In particular, if the agent’s subsistence consumption is equal to zero, i.e. if
the agent has homothetic preferences, then the present value of his disposable income
is positive at all times since and, as a result, his portfolio share is a decreasing function
of financial wealth.

Since $\lambda_1 = 0$ the agent’s mortality rate is purely exogenous and, as a result, so is the
effective discount rate. Since consumption and investment are then separated decisions,
exogenous discounting does not affect investment and mortality is irrelevant for health
investment rules. From equation (19), the optimal health investment is proportional to
the agent’s health status but independent of his financial wealth. As a result, the health
investment share

$$I_0^*(t, W, H) = \frac{I_0(t, H)}{W} = \frac{H}{W} (\alpha B(t))^{\frac{1}{1-\alpha}}$$

(29)
decreases in wealth, as required to explain the data, but counterfactually increases in
health. Equations (1) and (19) together imply that the optimal growth rate of health is
deterministic and independent from the agent’s health status. It follows that changes in
the agent’s health status have no impact on the returns to health investments. On the
other hand, the income effect of health is still present and is the only driving force behind
the comparative statics of health investment. As the agent’s health status improves,
the present value of his disposable income increases and, since returns are unaffected,
the agent increases his health investment.

The restriction of the model studied in this section abstracts from the mortality
reducing effects of health investments and only accounts for the impact of health through
the agent’s income. This specification allows to reproduce the fact that empirical portfol-
io shares increase in both health and financial wealth, with the latter property obtaining
when the agent’s human capital does not cover his subsistence consumption needs.
In accordance with the data, the model also produces health investment shares that are decreasing in financial wealth. However, the model counterfactually predicts that healthier agents should invest more in their health. In the next section we reintroduce health dependent mortality in order to verify whether or not this additional channel of health dependence is able to explain the observed patterns of health investment without altering the favorable performance of the model with respect to portfolio.

3.2 Health dependent mortality

When $\lambda_1 \neq 0$ the agent’s mortality rate depends on his health status. In this case, one can no longer determine the optimal health investment policy independently of the optimal portfolio and consumption strategy since, as shown by equation (14), the agent’s objective function now depends on his health status through the mortality rate’s impact on the endogenous discount rate.

Using standard calculations (e.g. Duffie and Epstein, 1992) we obtain that the Hamilton-Jacobi-Bellman (HJB) equation associated with the agent’s optimization problem is given by

$$\lambda(H)V = \max_{(\pi,c,I)} \left\{ L^{\pi,c,I}V + f(c, V) - \frac{\gamma}{2V}(\pi\sigma W V_W)^2 \right\}$$  \hspace{1cm} (30)

where

$$L^{\pi,c,I} = \partial_t + (H^{1-\alpha} I^\alpha - \delta H)\partial_H$$

$$+ ((r + \pi \sigma \theta) W + Y - c - I)\partial_W + \frac{1}{2}(\pi\sigma W)\partial_{WW}$$

is the differential operator associated to the agent’s wealth and health status under the strategy $(\pi, c, I)$. In the above equations, an alphabetical subscript indicates a partial derivative and we have omitted the dependence of the functions on the agent’s age, wealth and health status for ease of notation.
Maximizing the right hand side of the HJB equation (30) with respect to \( \pi, c \) and \( I \) we find that the optimal rules can be computed as

\[
\pi^* = \frac{\theta V V_W}{\sigma W(\gamma V^2_W - V V_W W)}, \tag{31}
\]

\[
c^* = a + V \left( \frac{\rho}{V_W} \right)^\varepsilon, \tag{32}
\]

\[
I^* = H \left( \frac{\alpha V_H}{V_W} \right)^{\frac{1}{1 - \alpha}}. \tag{33}
\]

Substituting these expressions into the HJB equation and simplifying the resulting expression gives a nonlinear partial differential equation for the agent’s indirect utility.\(^29\) Unfortunately, no closed form solution to this equation is known except for the case of health independent mortality which was solved in the previous section. Nonetheless, as we now explain, we can use the explicit solution to this special case as a benchmark in order to obtain an approximate solution for the general case by expanding the indirect utility in powers of \( \lambda_1 \).

Denote by \( n \) the order of the expansion and let us expand the indirect utility function of a living agent as

\[
V \approx V_0 + \lambda_1 V_1 + \cdots + \frac{1}{m!} \lambda_1^m V_m + \cdots + \frac{1}{n!} \lambda_1^n V_n.
\]

Here \( V_0 = V_0(t, W, H) \) is the agent’s indirect utility function in the case of health independent mortality and

\[
V_m = V_m(t, W, H) = \frac{\partial^m}{\partial \lambda_1^m} V(t, W, H) \bigg|_{\lambda_1=0}
\]

is the \( m \)th order correction induced by the presence of health dependent mortality. Substituting this approximation of the indirect utility function into the HJB equation and expanding the resulting equation in powers of \( \lambda_1 \) gives a sequence of partial differential equations which can be solved recursively starting from the known function \( V_0(\cdot) \). Once the correction terms have been computed up to the desired order of expansion, one can

\(^29\)For details see equation (59) in the appendix.
obtain an approximation of the optimal portfolio, consumption and health investment by substituting the expansion of the indirect utility function into equations (31), (32) and (33) and expanding the resulting expressions in powers of $\lambda_1$.

In order to implement the above method it is necessary to select the accuracy of the approximation by fixing the number of terms to include in the expansion. Since the intensity parameter $\lambda_1$ is expected to be small, we can be reasonably confident that the expansion method already delivers good approximations of the indirect utility function and optimal rules at the first order. While higher order approximations can also be computed, we will restrict ourselves to this first order solution because it allows for an intuitive analysis of the optimal rules.

**Theorem 2** Assume that equations (17), (25) and

$$A + \xi \left( (\alpha B(T))^\frac{\alpha}{1 - \alpha} - \delta \right) > r - \lambda_0 + \frac{\theta^2}{\gamma} \geq 0$$

(34)

hold where $A$ and the function $B(\cdot)$ are defined as in Theorem 1. Up to a first order approximation, the agent’s indirect utility is

$$V(t, W, H) = V_0(t, W, H) - \frac{\lambda_1}{H^\xi} \Delta(t)V_0(t, W, H)$$

(35)

and generates the approximate optimal portfolio, consumption and health investment strategy given by

$$\pi_1(t, W, H) = \pi_0(t, W, H),$$

(36)

$$c_1(t, W, H) = c_0(t, W, H) - \frac{\lambda_1}{H^\xi} \Delta(t)(1 - \varepsilon)AN(t, W, H),$$

(37)

$$I_1(t, W, H) = I_0(t, H) + \frac{\lambda_1}{H^\xi} \Delta(t)(\alpha B(t))^{\frac{\alpha}{1 - \alpha}}N(t, W, H).$$

(38)

In the above equations, $\Delta(\cdot)$ is a nonnegative function of the agent’s age which is defined in the appendix, $\eta = \alpha\xi/(1 - \alpha)$ and the functions $V_0(\cdot)$, $\pi_0(\cdot)$, $c_0(\cdot)$, $I_0(\cdot)$ and $N(\cdot)$ are defined as in Theorem 1.

---

30 This conjecture is confirmed by the structural estimation results of Section 4 which show that the value of $\lambda_1$ needed to fit the HRS data is of the order of $10^{-3}$. 

The restriction imposed by equation (34) is a transversality condition which guarantees that the first order correction to the agent’s indirect utility is well defined. Under this restriction, equation (35) and the nonnegativity of the functions \( V_0(\cdot) \) and \( \Delta(\cdot) \) imply that the presence of health dependent mortality reduces the agent’s indirect utility. The intuition behind this result is straightforward. Indeed, adding a health dependent part to the mortality rate triggers a decrease in the survival probability and hence also a decrease in the indirect utility since the agent has a preference for life.

Compared to the case of health independent mortality, the presence of health dependent mortality decreases the agent’s life expectancy and leads to two conflicting effects whose interaction determines the change in the agent’s optimal consumption. First, an increase in the mortality intensity reduces the implicit value of the agent’s income and, hence, incites him to decrease his consumption through a wealth effect. Second, a reduction in the agent’s life expectancy reduces the need to save for the future and, thus, leads the agent to increase his consumption through an intertemporal substitution effect. When the elasticity of intertemporal substitution is smaller than unity, the wealth effect dominates and the agent decreases his consumption relative to the health independent mortality case. Conversely, when the elasticity of intertemporal substitution is greater than unity, the substitution effect dominates and the agent increases his consumption. Exact cancelation of the two effects occurs when \( \varepsilon = 1 \) in which case mortality, be it health dependent or not, has no impact on the optimal consumption plan.

Equation (36) shows that, although it affects the repartition of the agent’s wealth between financial and human capital, the presence of health dependent mortality has no first order effect on his optimal portfolio share. As in the case of health independent mortality, this is due to the fact that portfolio rules are insensitive to discounting considerations in the absence of dynamic hedging motives. Indeed, the first order portfolio is obtained by performing a perturbation of the agent’s problem around the optimal rules associated with the case of health independent mortality. Since the optimal health status associated with that case evolves in a deterministic way, it follows that the investment opportunity set which is relevant to the determination of the first order
rules is also deterministic and this implies that there is no first order correction to the agent’s portfolio.

Since the constant $\eta$ and the functions $B(\cdot)$, $\Delta(\cdot)$ and $N(\cdot)$ are nonnegative, equation (38) shows that health dependent mortality induces the agent to increase his health investment. The intuition behind this result is again straightforward. The presence of health dependent mortality mechanically increases the agent’s death intensity and, thus, decreases his life expectancy compared to the case of health independent mortality. Since the agent has a preference for life, he responds to this decrease in life expectancy by increasing his health investment in order to improve his health status and, thus, partially mitigate the impact of health dependent mortality. As can be seen from the fact that the right hand side of equation (38) depends on the agent’s wealth and health status, this in turn implies that health dependent mortality introduces substitution effects between health investment, consumption and financial investments at the optimum.

In order to better understand these substitution effects we now study the comparative statics of the health investment and portfolio shares with respect to the agent’s financial wealth and health status. Assume that $C(\cdot)$ is negative, for otherwise the optimal portfolio is a monotone decreasing function of financial wealth and let

$$I^*(t, W, H) \equiv \frac{I_1(t, W, H)}{W}$$

(39)

denote the agent’s health investment share. Using this definition together with equations (36) and (38) it is easily shown that the comparative statics of the agent’s health investment and portfolio shares can be represented graphically as in Figure 1 for some functions $G(\cdot)$, $\Pi(\cdot)$ and $\Pi(\cdot) \leq \Pi(\cdot)$ which are defined in the appendix. Since health dependent mortality has no first order effect on the optimal portfolio share, the comparative statics of the first order portfolio share are exactly the same as those discussed in the previous section. We will therefore focus our analysis on the comparative statics of the health investment share.

Consider first the effect of a change in the agent’s financial wealth. As financial wealth increases, the liquidity constraint induced by the presence of minimal consumption expenditures softens and, consequently, the agent has additional capital that
Figure 1: Comparative statics of the first order rules

Notes: This figure illustrates the comparative statics of the first order portfolio and health investment shares predicted by Theorem 2 under the assumption that $C(\cdot) \leq 0$. The solid line plots the minimal level of financial wealth needed to cover subsistence consumption needs; the vertical dotted lines plot the loci of points where $I^s_W \equiv 0$ and $\pi^s_W \equiv 0$; and the dashed curve indicates the financial wealth and health status levels where $I^s_H \equiv 0$.

can be allocated to health investment, consumption and/or financial investments. To decide on the allocation of this surplus, the agent compares the return on health investments to those of the other available opportunities. The latter are independent of the agent’s health status but the former is not. In particular, the specification of the health production function and of the mortality rate imply that the return on health investments decreases as the agent’s health status improves. The convexity of both the health adjustment costs and the intensity function implies that, for low health status (below $H(\cdot)$) this return is very high and encourages the agent to increase his health investment share in response to an increase in financial wealth. In contrast, for high health status (above $H(\cdot)$) the return on health investments is much lower and this prompts the agent to decrease his health investment share at the benefit of portfolio, consumption and/or savings. Exact cancelation of the two effect occurs along
the vertical locus $H = H(\cdot)$ where the optimal health investment share is insensitive to changes in financial wealth.

An improvement in the agent’s health status leads to two opposite effects. First, a better health status implies a lower return to health investments through a lower mortality rate and a lower effectiveness of health investments. Both reductions encourage the agent to decrease his health investment. Second, an improvement in health status relaxes the agent’s liquidity constraint through an increase in the present value of disposable income and, hence, encourages the agent to increase his health investment share. At low financial wealth (below $G(\cdot)$) the marginal relaxation of the agent’s liquidity constraint dominates the decrease in the return to health investments and, consequently, the agent increases his health investment share in response to an improvement in his health status. Conversely, at high financial wealth (above $G(\cdot)$) the marginal relaxation of the agent’s constraint is dominated by the decrease in the return to health investments and the agent decreases his health investment share. Exact cancelation of the two effects occurs along the locus $W = G(\cdot)$ where the optimal health investment share is insensitive to changes in the agent’s health status.

Interestingly, the region of the state space below the locus $W = G(\cdot)$ and to the left of the locus $H = H(\cdot)$ is characterized by health investment shares that increase with respect to both financial wealth and health status. In this region, an adverse financial shock is followed by a reduction in the health investment share since the agent’s resources are barely sufficient to cover his minimal consumption needs. This results in lower future health and hence in lower future income to which the agent reacts by reducing his health investment share even further. Put differently, this region of the state space can be seen as a poverty trap in which adverse shocks get amplified through reductions in the optimal health investment share.

The above discussion shows that, contrary to the partial success of its health independent mortality counterpart, the model with health dependent mortality can potentially reproduce the empirical patterns of portfolio and health investment shares. In
particular, there exists a non trivial region of the state space given by:

$$\mathcal{A}_t = \left\{(W, H) \in \mathbb{R} \times \mathbb{R}_+: W \geq G(t, H) \text{ and } H(t) \leq H \leq \overline{H}(t)\right\}$$

where predicted portfolio shares profactually increase with financial wealth and health status while predicted health investment shares profactually decrease with financial wealth and health status. Admittedly, the performance of the model will depend on the deep parameters which determine the exact positions of the loci in Figure 1 and on the position of the observed levels of financial wealth and health status with respect to these loci. Taken together, these two elements highlight the need for a thorough empirical investigation of our model. This is the issue we address in the next section.

4 Econometric analysis

In this section, we perform an econometric evaluation of our model. We first outline the estimation strategy, then we present the estimated parameters. Finally, we discuss additional implications of our empirical results. The estimation relies on the same cross-sectional data set introduced in Section 1. Indeed, even though the theoretical model is developed in a dynamic setting, its solutions can be used to estimate the deep parameters from both a cross-sectional and panel perspective. We select the former to facilitate the estimation and leave the latter for future research agenda.

4.1 Econometric model

The econometric model used to estimate the structural parameters is given by the optimal first-order rules derived under endogenous mortality in Theorem 2. Due to the lack of reliable consumption data in HRS for a sufficiently large sample, we do not consider the optimal consumption rule and focus instead on the portfolio and investment rules only.\(^{31}\) Specifically, an agent \(j = 1, 2, \ldots\) in our sample is characterized by his age \(t_j\), financial wealth \(W_j\), self-reported health status \(H_j\), observed portfolio shares \(\pi_j\) and

\(^{31}\)Hurd and Rohwedder (2005) report that 3,800 agents out of 5,000 selected individuals returned the 2001 and 2003 HRS- Consumption and Activities Mail Survey (CAMS) questionnaires on consumption patterns. See also Blau (2008) for analysis and discussion.
health investment levels $I_j$. The econometric model is estimated in levels rather than shares\footnote{Although the theoretical model is fully amenable to both, the choice of levels instead of shares is made to avoid extreme values for shares of wealth whenever $W_j = 0$. This allows us to use the full sample instead of estimating the model over those agents with positive net financial wealth only.} and is given by:

$$
\pi_j W_j = \theta_{\pi,0}(t_j)W_j + \theta_{\pi,1}(t_j)H_j + \theta_{\pi,2}(t_j) + \epsilon_{\pi,j}, \quad (40)
$$

$$
I_j = \theta_{I,1}(t_j)H_j + \theta_{I,2}(t_j)H_j^{-\xi}W_j + \theta_{I,3}(t_j)H_j^{1-\xi} + \theta_{I,4}(t_j)H_j^{-\xi} + \epsilon_{I,j}, \quad (41)
$$

with

$$
[\epsilon_{\pi,j}, \epsilon_{I,j}] \sim N \left(0, \Sigma \right).
$$

The choice of the above functional form is dictated by equations (36) and (38) which also give the closed-form expressions for the parameters $\theta_{\pi}(t_j) = \{\theta_{\pi,0}(t_j), \theta_{\pi,1}(t_j), \theta_{\pi,2}(t_j)\}$ and $\theta_{I}(t_j) = \{\theta_{I,1}(t_j), \theta_{I,2}(t_j), \theta_{I,3}(t_j), \theta_{I,4}(t_j)\}$ of the econometric model as function of the deep parameters of the model. The error terms $[\epsilon_{\pi,j}, \epsilon_{I,j}]$ can naturally be interpreted as approximation errors resulting from the first-order expansion to the optimal rules. The Gaussian assumption is necessary in order to compute the likelihood function, as is discussed next.

The estimation of the econometric model poses several challenges. First, even though our theoretical model characterizes optimal rules in both the pre- and post-retirement phases, estimating pre-retirement rules requires solving a set of differential equations at each iteration of the search algorithm and is considerably more difficult than for post-retirement rules. We consequently restrict the employment status to $i = r$ and estimate the model over retired agents (i.e. over 65) only. A direct consequence of this choice is that the parameters in (40) and (41) are then age-independent, i.e. $\theta_{\pi}(t_j) = \theta_{\pi}$ and...
\( \theta_I(t_j) = \theta_I, \forall t_j \) and only a function of the deep parameters:

\[
\begin{align*}
\theta_{\pi,0} &= \frac{\theta}{\gamma\sigma}, & \theta_{I,1} &= (\delta + J)^{\frac{1}{\pi}}, \\
\theta_{\pi,1} &= \theta_{\pi,0}B, & \theta_{I,2} &= \frac{\alpha\lambda_1 \xi(J + \delta)}{(1 - \alpha)(\xi J + A)}, \\
\theta_{\pi,2} &= \theta_{\pi,0}C, & \theta_{I,3} &= \theta_{I,2}B, \\
\theta_{I,4} &= \theta_{I,2}C,
\end{align*}
\]

where \( C \equiv C(T) = (y^* - a)/r \), the constant \( A \) is defined as in Theorem 1 and the pair \((J, B)\) solves the system of equations given by

\[
\begin{align*}
J &= (\alpha B)^{\frac{\alpha}{1 - \alpha}} - \delta, \\
B &= \frac{\beta^r}{r + \alpha\delta - (1 - \alpha)J}.
\end{align*}
\]

A second difficulty is that a sizable percentage of the portfolio shares are reported at zero. Moreover, it is reasonable to suspect that agents could not invest negative amounts in their health (i.e. sell part of their health) if they wanted to. This implies that our dependent variables are likely left-censored at zero and that a multivariate Tobit estimator is warranted. Third and related, the theoretical restrictions on \( \theta_\pi \) and \( \theta_I \) in \((42)\) are highly nonlinear and these nonlinearities are compounded by the Tobit estimator, thereby making the estimation particularly challenging.

Fortunately, we may observe that —conditional upon a given value for the parameter \( \xi \) —the unrestricted econometric model in \((40)\) and \((41)\) is linear in the parameters. This suggests resorting to a two-stage approach. In the first stage, we estimate the unrestricted reduced form (URF) parameters \( \theta_\pi, \theta_I \) without imposing any constraint by using a ML estimator constructed upon a bivariate Tobit density. In the second, we infer the structural parameters of interest by using a minimum distance estimator between the estimated parameters \( \hat{\theta}_\pi, \hat{\theta}_I \) and their theoretical counterparts given in \((42)\). This two-step procedure presents several advantages over a single-step, fully structural estimation. First, it is considerably easier to estimate and can be shown to yield consistent estimates of the structural parameters through the invariance principle of ML estimators. Second
and as is discussed below, it provides a set of first checks of the theoretical model through the signs of the URF parameters.

Given that the first-stage estimation yields seven free parameters, we can potentially identify up to seven structural parameters using \((42)\). In order to augment identifiability, we also incorporate the relevant theoretical constraints in the second step such that the structural parameters are identified subject to the nonlinear transversality inequalities \((17), (25)\) and \((34)\).\(^{33}\) Because the model incorporates more than seven structural parameters, not all can be identified and we follow standard approaches in calibrating a subset of the full parametric set, estimating the remaining deep parameters and verifying robustness to key calibrated values.

First, the parameters \(y^r, \beta^r\) of the income process \((5)\) are estimated jointly by appending the exogenous continuous process to the bivariate Tobit model of the optimal rules and using a mixture ML estimation.\(^{34}\) Second, a natural choice is to calibrate the parameters of the financial markets \((r, \sigma, \mu)\), as well as the subjective discount rate \((\rho)\) for which ample literature provides guidance. Finally, the convexity of the Poisson intensity \((\xi)\) does play a key role in the first-stage estimation of the model through its scaling of the health status in the health investment equation. Because we have very little information on this parameter, we consequently let it vary between an upper and lower bound and verify its relevance through ex-post regularity checks which are discussed below. Table 6 summarizes the calibrated and estimated parameter subsets.

\[\text{[Insert Table 6 about here]}\]

Several hypotheses can be tested through the joint estimation of the structural parameters. First, the estimated preference parameters allow us to test the null hypotheses of no aversion to a-temporal risk \((\gamma = 0)\), of no subsistence consumption \((a = 0)\), of inelastic inter-temporal substitution of deterministic consumption paths \((\varepsilon = 0)\), as well as the null of time additive preferences in the absence of mortality risk \((\varepsilon = 1/\gamma)\). Second, the health dynamics parameters can be used to test the null hypotheses that

\(^{33}\)In practice we also used the life expectancy constraint \((45)\) associated with Proposition 2 discussed below.

\(^{34}\)Given that only 48 elders out of our sample of 10,735 reported no income (earnings, capital income and pensions plus transfers), resorting to an uncensored distribution for the income process \((5)\) is warranted.
the agent has no control over the evolution of his health status \( (\alpha = 0) \), or that he does not face convex adjustment costs \( (\alpha = 1) \) in health investments. We can also test that health does not depreciate exogenously \( (\delta = 0) \). Finally, regarding the death intensity, we are able to test the null hypotheses that there is no exogenous mortality component \( (\lambda_0 = 0) \), or that the agent has no control over mortality risk \( (\lambda_1 = 0) \).\(^{35}\)

4.2 Results

4.2.1 Unrestricted reduced-form parameters

Table 7 presents the maximum likelihood estimates of the URF trivariate mixture model of the continuous income process (eq. (5), Panel A), as well as the Tobit processes for risky asset levels (eq. (40), Panel B) and health investments levels (eq. (41), Panel C).\(^{36}\) We should emphasize that all the following results are robust to adding socio-economic covariates such as age, education, gender or race to the estimated system.\(^{37}\) The estimates are obtained for a scaling of \( 10^{-6} \) applied to all nominal variables \( (I_j, W_j, Y_j) \) and by expressing the polytomous self-reported health variable in numerical units 1 (poor) to 5 (excellent). Regarding the effect of the convexity parameter \( \xi \), an extensive search procedure over this parameter reveals that values larger than 3.0 provide the best performance in terms of convergence, fit and compliance with theoretical restrictions. To illustrate robustness, we provide results for \( \xi \in \{3.0, 3.6, 4.4\} \). Since it appears only in equation (41) and because the estimated cross-equations correlations between the error terms are low, this parameter has no impact on the unrestricted labor income and portfolio parameter estimates and affects only the investment levels.

[Insert Table 7 about here]

Combining the URF parameters with the theoretical restrictions summarized in (42) provides a first indication on the model’s ability to reproduce the data. First, the parameter \( \theta_{\pi,0} \) is significantly positive and, given a positive financial risk premia, \(^{35}\)Even though the parameter \( \xi \) is calibrated rather than estimated, note that it allows us to characterize the importance of the convexity of the endogenous mortality if the null hypothesis of \( \lambda_1 = 0 \) is rejected.\(^{36}\)For brevity, we omit the full reporting of the scedastic parameters which can be obtained upon request.\(^{37}\)These results are available from the authors upon request.
is consistent with positive risk aversion. Second, the restrictions indicate that the parameters $\theta_{\pi,1}, \theta_{I,1}, \theta_{I,2}, \theta_{I,3}$ should be positive through the non-negativity of $A, B, \Delta$ and of the deep parameters. Indeed, all parameters are significantly positive, with the exception of $\theta_{I,1}$ (when $\xi = 3.0$) and $\theta_{I,2}$ (for all $\xi$), both of which have the correct sign but are not statistically significant. Third, the previous analysis of the portfolio rules reveals that the NPV of fixed labor income net of subsistence, $C$, should be negative for portfolios to be profactually increasing in wealth at sufficiently high levels of wealth. Given that $\theta_{\pi,0} > 0$, this amounts to the restriction $\theta_{\pi,2}, \theta_{I,4} < 0$ which is indeed verified by the URF parameter estimates reported in Table 7.

### 4.2.2 Structural parameters

Overall, the URF parameters provide an encouraging first evaluation of the model. All the seven reduced-form parameters have the correct signs and are, with one exception, all significant. Our next objective is to revert the structural parameters of interest in the second step of our estimation strategy. This is obtained by minimizing the distance between the URF parameters and their theoretical counterparts listed in (42), subject to the relevant regularity constraints. Table 8 reports these second-step point estimates for the structural parameters. In an unreported regularity check, we first verify and confirm that the estimated model satisfies all the required transversality conditions, whether for the exogenous or the endogenous mortality.\footnote{\textsuperscript{38}} Importantly, the preferences, health dynamics and mortality parameters are all significant at the 1\% level.

\[\text{[Insert Table 8 about here]}\]

First, turning to preference parameters (Panel A), we find that all the estimates for risk aversion $\gamma$ are very robust across calibrated $\xi$, are consistent with aversion to a-temporal risk and are realistic compared with the usual standard (e.g. Mehra and Prescott, 1985). Next, the subsistence consumption parameter $a$ is also robust across $\xi$. The fact that it is significant is consistent with our theoretical finding that non-homothetic preferences are necessary to reproduce the comparative statics of portfolio

\footnote{\textsuperscript{38}The full results can be obtained upon request.}
rules, notably that they increase in wealth. The estimated level corresponds to a minimal consumption of $0.0247 \times 10^6 = \$24,700$ a value which is lower than the mean labor income of $\$28,709$ for agents over 65 in our sample, but larger than the fixed part of the income process for retired agents ($y^r = \$9,096$). This last result is consistent with our URF estimates pointing towards a negative value for $C$. Moreover, the parameter for the elasticity of inter-temporal substitution $\varepsilon$ is significantly lower than 1 and reasonably robust across $\xi$. This indicates that agents substitute consumption poorly across time and is consistent with similar findings in the literature (e.g. Engelhardt and Kumar, 2009; Lee, 2008; Biederman and Goenner, 2008; Saltari and Ticchi, 2007; Vissing-Jørgensen, 2002, provide recent examples). Finally, the null hypothesis of time additive preferences in the absence of mortality risk which corresponds to $\varepsilon = 1/\gamma$ is strongly rejected.

Next, the estimates for the health dynamics (Panel B) are reasonably robust to the calibrated values for $\xi$, with all the qualitative results remaining valid. First, we identify a low value for the Cobb-Douglas parameter $\alpha$ that is significantly different from both 0 and from 1 as well as a fairly high depreciation rate for the health stock $\delta$. This implies that the agent is able to, but faces important convexities in making adjustment to the health stock and that health depreciates rapidly in the absence of such investments. Both results could reflect our choice of retired individuals in our HRS sub-sample for which health adjustments appear to be at the same time more costly and more consequential.

Finally, we find in Panel C a significant $\lambda_0$ pointing towards an incompressible component to mortality risk. As shown in eq. (46) below, the exogenous mortality horizon is $1/\lambda_0$, corresponding to 12–13 years at our point estimates. Given an average age of 75 in our sample, these estimates thus appear reasonable compared to the data.\(^{39}\) Moreover, all the estimates of the endogenous mortality parameter are low; this adds confidence in the adequacy of our perturbation method constructed around a small value for $\lambda_1$. We nonetheless reject the null that this parameter is zero. This is consistent with our theoretical model which predicts that the exogenous mortality model ($\lambda_1 = 0$)

\(^{39}\)For example, the US Life Tables report an average remaining lifetime of 12.6 years for age 74–75 for the entire population (Arias, 2007, Tab. 1).
is unable to reproduce the comparative statics of health investments, in particular that they fall in health.

4.3 Discussion

To the best of our knowledge, the parameters of the health dynamics (1) and of the Poisson mortality (2) have not been jointly estimated in the literature. As a result, there is no benchmark against which our estimates can be compared. Nonetheless, a possible check can be performed by contrasting the life expectancy induced by these estimates to those reported in the literature. For that purpose, we start by calculating the life expectancy of a retired agent that is predicted by the model.

**Proposition 2** Assume that equations (17), (25), (34) and

\[
\Phi^{-1} = \lambda_0 + \xi \left( (\alpha B(T) \right)^{1/\alpha} - \delta > 0 \tag{45}
\]

hold true. Up to a first order approximation, the life expectancy of a retired agent is independent of wealth and given by

\[
\ell(H) = \frac{1}{\lambda_0} \left( 1 - \frac{\lambda_1}{H^\xi} \Phi \right). \tag{46}
\]

Proposition 2 reveals that, up to a first order, the remaining time horizon of a retired agent is given as an increasing function of the agent’s health status exclusively. Consequently, the life expectancy in equation (46) can be evaluated at the calibrated value for \( \xi \) and the corresponding point estimates \( (\lambda_0, \lambda_1, \alpha, \delta) \) reported in Table 8, for \( H \in \{1, 2, 3, 4, 5\} \). We then compare these theoretical estimates with the life expectancy estimated by Lubitz et al. (2003) for an individual aged 70, again for various self-reported health levels. These figures are reported in Panel A of Table 9 and show that our model is able to fit the data quite well even though we somewhat underestimate the health gradient. This last caveat may be explained by the high value of the convexity parameter \( \xi \) which tends to dampen the effect of health on the mortality intensity.

[Insert Table 9 about here]
In the lower panel of Table 9 we also report the threshold levels ($H, \overline{H}$) as well as the corresponding values of the functions $P(\cdot)$ and $G(\cdot)$ which determine the position of the various loci in Figure 1. It will be recalled that the wealth effects on portfolios and health investment shares can be reproduced if the health level is in the admissible range of $\mathcal{A}_t$ corresponding to $H \in [\underline{H}, \overline{H}]$. The estimated thresholds are slightly above 1 and above 5 and indicate that it is the case; the vast majority (87%) of our sample is contained in the admissible health region. Put differently, our model captures the wealth effects on portfolios and health investment remarkably well. The corresponding estimate for $P(H)$ is close to 0.25.\[^{40}\] This value is relatively large for our financial wealth estimates which reports a mean wealth level of 0.123 (i.e. $122,573 \times 10^{-6}$, see Table 1). This is confirmed by the high values for $G(H), G(\overline{H})$. Put differently, our model has more difficulty in reproducing the health effects on the observed portfolios and health investment for the poor and unhealthy agents.

Two interpretations of this last result may be invoked. First, the subsistence level may admittedly be difficult to identify in the absence of consumption data. Our relatively large estimate for the subsistence consumption parameter $a$ translates into a large estimate for $C = (y^r - a)/r$ and is, thus, conducive to a large negative value for the net present value of disposable labor income $P(H) = BH + C$. Second, these results are consistent with a low participation in risky asset markets for a non-negligible share of our sample. Although partially controlled for through the Tobit estimation, the estimated parameters are likely capturing those agents who actually do participate in the stock market and are characterized by higher financial wealth and better health levels.

5 Conclusion

This paper shows that the observed co-movements between financial and health statuses and investments can jointly be explained by a parsimonious model that integrates two well-accepted, but otherwise segmented, Health and Financial Economics frameworks. Both our theoretical and econometric results confirm that endogenous mortality, positive

\[^{40}\text{The value for } P(\overline{H}) \text{ is identically 0.}\]
health elasticities of labor income, convex health adjustment costs and generalized recursive, non-homothetic preferences are key ingredients in understanding individual financial and health choices.

Despite its parsimony, we find it reassuring that the proposed model fares so well. We believe it speaks in favor of it being used as a workhorse for additional developments either along the lines we have suggested or along others. An avenue that we find particularly promising is the cyclical implications of the model. If adverse economic conditions in recessions lead to adjustments in health investments and if the resulting changes in the health status affect the willingness to hold risky financial assets, then this might point towards interesting predictions for the business cycle properties of asset markets. We leave these issues for a future research agenda.

We have voluntarily selected a high level of abstraction at a cost of realism. Many interesting and possibly relevant issues have thus been set aside. For example, our choice of deterministic health, although standard in Health Economics, may fruitfully be questioned. We could conjecture that increased background health risk leads to even more prudent portfolios or to the maintenance of a health buffer stock. Conversely, introducing health, work or life insurance as well as bequests might affect the results in the opposite way. Finally, by focusing on the cross-sectional dimension, we have not fully exploited all the information contained with the data set or the model. Estimating the latter in the panel dimension could provide for interesting subsequent empirical work.

A Proofs

Proof of Proposition 1. Using equation (16) and the fact that, in the absence of wealth effects, the health status is deterministic we deduce that the present value of the agent’s disposable income can be written as

\[ P(t, H_t) = C(t) + \sup_{I \geq 0} \int_t^\infty e^{-r(s-t)}(\beta(s)H_s - I_s)ds, \quad (47) \]

where \( \beta(\cdot) \) is the deterministic function defined by

\[ \beta(t) = Y_H(t, H) = \beta^e + 1_{\{T \leq t\}}(\beta^f - \beta^e). \]

Let \( P(t, H) = P(t, H) - C(t) \) denote the value function of the optimization problem on the right hand side of equation (47). The dynamics of the health status and the linearity of the objective function imply that \( P(\cdot) \) is increasing and homogenous of degree one with respect to health. Using these properties it can be shown that \( P(\cdot) \) and the optimal investment policy are given by

\[
\begin{align*}
P(t, H) &= B(t)H, \\
I_0(t, H) &= H(\alpha P_H(t, H))^{\frac{1}{1-\sigma}} = H(\alpha B(t))^{\frac{1}{1-\sigma}},
\end{align*}
\]
for some nonnegative function $B(\cdot)$ of the agent’s age which solves the Hamilton–Jacobi–Bellman equation

$$(r + \delta)B(t) = B'(t) + \beta(t) + \max_{x \geq 0} (x^\alpha B(t) - x)$$

$$= B'(t) + \beta(t) + \Phi B(t)^{1/\alpha},$$

subject to the transversality condition

$$\lim_{t \to \infty} e^{-rt} B(t) H_0^t = 0,$$

where $H_0^t$ denotes the path of the agent’s health status under the optimal investment strategy and we have set $\Phi = (1 - \alpha)\alpha^{1/\alpha}$.

Since the function $\beta(\cdot)$ becomes age independent after the retirement date, the solution to the above ODE is given by

$$B(t) = 1_{\{T > t\}} B_e(t) + 1_{\{T \leq t\}} B_r$$

for some pair $(B_r, B_e(\cdot))$ such that $B_r \geq 0$ solves the steady state equation

$$g(B_r) = \beta^r - (r + \delta)B_r + \Phi B_r^{1/\alpha} = 0,$$

and the function $B_e(\cdot)$ solves equation (48) on the time interval $[0, T]$ subject to the value matching condition $B_e(T) = B_r$. Furthermore, for any such solution the associated health status process satisfies

$$dH_0^t = H_0^t \left( (\alpha B_r)^{\frac{2}{\alpha}} - \delta \right) dt,$$

for all $t \geq T$ and it follows that the transversality condition (49) is equivalent to the requirement that $g'(B_r) < 0$. 

49
Summarizing the above results, the problem reduces to finding a constant $B_r \geq 0$ and a function $B_e(\cdot) \geq 0$ such that

$$g(B_r) = 0 > g'(B_r),$$  \hspace{1cm} (52)

$$B_e'(t) = (r + \delta)B_e(t) - \beta e - \Phi B_e(t)^{1-\alpha},$$  \hspace{1cm} (53)

$$B_e(T) = B_r.$$  \hspace{1cm} (54)

Unfortunately, these equations do not admit closed form solutions in general so we will have to prove that, under condition (17), there exists a unique solution which can then be computed numerically.

Straightforward analysis shows that the function $g(\cdot)$ satisfies $g(0) = \beta^r > 0$ as well as $g'(0) = -(r + \delta) < 0$ and attains a unique minimum over the positive real line. The value of this minimum is explicitly given by

$$\min_{x \geq 0} g(x) = g\left((1/\alpha)(r + \delta)^{1/\alpha - 1}\right) = \beta^r - (r + \delta)^{1/\alpha}.$$  

Under condition (17), the minimal value is negative and it follows that there exists a unique nonnegative $B_r$ which satisfies the requirements of equation (52). Given $B_r$, the existence of a unique nonnegative solution to the boundary value problem in equations (53) and (54) follows from standard results on first order ODEs.

**Proof of Theorem 1.** When the mortality rate is independent of the health status, the agent’s problem is equivalent to that of equation (23) given the initial capital $N(t, W, H)$. In particular, the optimal investment is the one of Proposition 1 and the optimal consumption, optimal portfolio and value function can be computed as

$$c_0 = a + x_0,$$

$$\pi_0 = \nu_0 N(t, W, H)/W,$$

$$V_0(t, W, H) = F(t, N(t, W, H)),$$
where \( F(\cdot) \) and \((x_0, \nu_0)\) denote, respectively, the value function and the optimal strategy for the problem of equation (23).

Following Svensson (1989), Duffie and Epstein (1992) and Duffie and Lions (1992) among others we have that the Hamilton-Jacobi-Bellman equation associated with the latter problem is given by

\[
\lambda_0 F = \max_{(x, \nu)} \left\{ L_{x, \nu}^N F + f(x, a, F) - \frac{\gamma}{2F}(\nu \sigma NF_N)^2 \right\}
\]

subject to the transversality condition

\[
\lim_{t \to \infty} e^{-\lambda_0 t} E_0[F(t, N^0_t)] = 0,
\]

where \( N^0 \) denotes the path of the agent’s total disposable wealth under the optimal consumption and portfolio strategy and

\[
L_{x, \nu}^N = \partial_t + ((r + \nu \sigma \theta)N - x)\partial_N + \frac{1}{2}(\nu \sigma N)^2\partial_{NN}
\]

is the differential operator associated to \((t, N)\) under the strategy \((x, \nu)\). Since the agent’s faces an infinite horizon problem with a constant investment opportunity set and does not receive any income through time, it must be the case that \( F(\cdot) \) is time independent. On the other hand, the specification of the agent’s preferences and the dynamics of the process \( N \) in equation (22) imply that \( F(\cdot) \) is increasing and homogenous of degree one with respect to the agent’s total disposable wealth.

Using these properties in conjunction with HJB equation, we obtain that the value function and the optimal strategy are given by \( F(N) = \phi N \) and

\[
x_0 = \rho^\epsilon \phi^{1-\epsilon} N,
\]
\[
\nu_0 = \theta / (\gamma \sigma),
\]
for some nonnegative constant $\phi$ which solves

$$\lambda_0 \phi = \max_{(x, \nu)} \left\{ \phi (r + \nu \sigma \theta - x) + f (x + a, \phi) - \frac{\gamma}{2} \phi (\nu \sigma)^2 \right\}$$

This equation admits a well-defined solution if and only if the constant $A$ of equation (25) is strictly positive. In this case, $\phi = \rho (A/\rho)^{1/2}$ and substituting this into the definition of the optimal consumption plan we conclude that $x_0 = AN$ as required.

In order to complete the proof we need to show that under condition (25) the above solution satisfies (55). Using equation (22) and the definition of the candidate optimal strategy we obtain that the agent’s total disposable wealth evolves according to

$$dN_t^0 = N_t^0 (r - A)dt + N_t^0 (\theta / \gamma) (dZ_t + \theta dt).$$

Combining this expression with well-known results on the expectation of the geometric Brownian motion gives

$$e^{-\lambda_0 t} E_0 [F(t, N_t^0)] = e^{-\lambda_0 t} E_0 [v N_t^0] = e^{-(\lambda_0 - r - \theta^2 / \gamma + A)t v N_0},$$

and it follows that condition (25) is necessary and sufficient for both the feasibility of $x_0$ and the validity of the transversality condition.

Proof of Theorem 2. The Hamilton-Jacobi-Bellman equation associated with the agent’s problem is given by (30) subject to

$$\lim_{t \to \infty} E_0 \left[ e^{-\int_{s=0}^{t} \lambda(H_s^*) ds} V(t, W_s^*, H_s^*) \right] = 0,$$

where $W^*$ and $H^*$ denote the path of the agent’s wealth and health status under the optimal strategy. Maximizing the right hand side of the HJB equation with respect to $\pi, c$ and $I$ gives the candidate optimal strategy of equations (32)–(33) and substituting these back into equation (30) shows that the HJB equation can be written as

$$\lambda(H)V = L^* V + f(c, V) - \frac{\gamma \theta^2 V V W W}{2(\gamma V W - V V W W)^2}$$

(59)
where

\[
L^* = \partial_t + ((I^*/H) - \delta)H\partial_H \\
+ ((r + \pi^*\sigma\theta)W + Y - c^* - I^*)\partial_W + \frac{1}{2}(\pi^*\sigma W)^2\partial_{WW}
\]

is the differential operator associated to the process \((t, H, W)\) under the optimal strategy.

Consider the approximate value function given by

\[
V(t, W, H) = V_0(t, W, H) + \lambda_1V_1(t, W, H) + o(\lambda_1^2)
\]

where the function

\[
V_1(t, W, H) = \left. \frac{\partial V}{\partial \lambda_1}(t, W, H) \right|_{\lambda_1=0}
\]

is the first order correction induced by the presence of health-dependent mortality. Substituting this approximation of \(V(\cdot)\) into the HJB equation and expanding the resulting expression to the first order in \(\lambda_1\) we obtain that the functions \(V_0(\cdot)\) and \(V_1(\cdot)\) solve the system of partial differential equations given by

\[
\lambda_0 V_0 = L^0 V_0 + f(c_0, V_0) - \frac{\gamma\theta^2 V_0 V_{0W}^4}{2(\gamma V_{0W}^2 - V_0 V_{0WW})^2},
\]

\[
\lambda_0 V_1 = L^0 V_1 + f_V(c_0, V_0)V_1 - \frac{V_0}{H^2} + \frac{\gamma\theta^2 (V_1 V_{0W}^4 - 2V_0^2 V_{0W}^3 V_{1W})}{2(\gamma V_{0W}^2 - V_0 V_{0WW})^2},
\]

where

\[
L^0 = \partial_t + (H^{1-\alpha} I_0^\alpha - \delta)\partial_H \\
+ ((r + \pi_0\sigma\theta)W + Y - c_0 - I_0)\partial_W + \frac{1}{2}(\pi_0\sigma W)^2\partial_{WW}
\]

is the differential operator associated to the optimal strategy \((\pi_0, c_0, I_0)\) of the health-independent mortality case. Similarly, substituting equation (60) into equations (32)–(33) and expanding the resulting expressions shows that a first order approximation of
the optimal strategy is

$$\pi_1 = \frac{\theta N(t, W, H)}{\gamma \sigma W} + o(\lambda_1^2),$$  \hfill (63)

$$c_1 = c_0 + \lambda_1 \frac{V_0 V_1}{V_0 W} + \varepsilon V_0 V_1 W + o(\lambda_1^2),$$  \hfill (64)

$$I_1 = I_0 + \lambda_1 \frac{V_0 V_1 W - V_1 V_0 W}{(1 - \alpha) V_0^2} + o(\lambda_1^2),$$  \hfill (65)

where the function $N(\cdot)$ is defined as in (21). Using the result of Theorem 1, the solution to (61) is given by

$$V_0(t, W, H) = \rho \left( A/\rho \right) \frac{1}{1 - \varepsilon} N(t, W, H).$$

Substituting this function into equation (62) and inspecting the resulting linear partial differential equation, we deduce that

$$V_1(t, W, H) = - \frac{\Delta(t)}{V_0(t, W, H)}$$  \hfill (66)

for some function $\Delta(\cdot)$ of the agent’s age which solves the first order ordinary differential equation

$$\Delta'(t) = \frac{\Delta(t)}{H} \left( \xi (\alpha B(t))^\frac{1}{1 - \alpha} - \xi \delta + A \right).$$  \hfill (67)

Since the function $B(\cdot)$ becomes age independent after the retirement date, the solution to the above ODE is given by

$$\Delta(t) = 1_{\{T > t\}} \Delta_e(t) + 1_{\{T \leq t\}} \Delta_r,$$

where $\Delta_r$ is the unique solution to the steady state equation

$$0 = \Delta_r \left( \xi (\alpha B_r)^\frac{1}{1 - \alpha} - \xi \delta + A \right) - 1,$$  \hfill (68)

and the function $\Delta_e(\cdot)$ solves the ordinary differential equation (67) on the time interval $[0, T]$ subject to the value matching condition $\Delta_e(T) = \Delta_r$. The unique solution to this
equation is given by
\[
\Delta e(t) = e^{-\int_t^T \zeta(s)ds} \Delta_r + \int_t^T e^{-\int_u^T \zeta(u)du}ds,
\]
where
\[
\zeta(t) = \xi(\alpha B(t))^{\alpha - 1} - \xi\delta + A.
\]
Now, substituting this function as well as \(V_0(\cdot)\) and \(V_1(\cdot)\) into equations (63), (64) and (65) gives the result reported in the statement and the proof will be complete once we show that the restrictions imposed by equations (25) and (34) are sufficient to guarantee that the approximate value function satisfies a suitable transversality condition.

To unveil the nature of this approximate condition, consider the original transversality condition in equation (58) and expand the quantity inside the expected value to the first order in \(\lambda_1\). This gives
\[
e^{-\int_0^t \lambda(H^*_s)ds} V(t, W^*_t, H^*_t) = e^{-\lambda_0 t} V_0(t, W^*_0, H^*_0) + \lambda_1 e^{-\lambda_0 t} (V_1(t, W^*_0, H^*_0) - \mathcal{H}_t^0 V_0(t, W^*_0, H^*_0)) + o(\lambda_1^2),
\]
where \(W^0\) and \(H^0\) denote the path of the agent’s wealth and health status under the optimal strategy \((\pi_0, c_0, I_0)\) of the health independent mortality case and we have set
\[
\mathcal{H}_t^0 = \int_0^t (H^*_s)^{-\xi} ds.
\]
Since the expectation of the first term on the right of equation (69) converges to zero due the transversality condition of the health-independent mortality case, this implies that the transversality conditions associated to the first order approximation can be formulated as
\[
\lim_{t \to \infty} E_0 \left[ e^{-\lambda_0 t} (V_1(t, W^*_t, H^*_t) - \mathcal{H}_t^0 V_0(t, W^*_0, H^*_0)) \right] = 0. \quad (70)
\]
Let $t \geq T$ and denote by $\Gamma_t$ the quantity in the above expectation. Using the definition of $H_0$ in conjunction with the dynamics of $H^0$ in equation (51) we obtain

$$H_t^0 = H_T^0 + \left(1/\xi\right)(H_T^0)^{-\xi} - (H_t^0)^{-\xi}.$$ 

where we have set $\xi = \xi(T)$. Combining this expression with equation (66) and using the definition of the function $N(\cdot)$ we obtain

$$E_0[\Gamma_t] = e^{-\lambda_0 t} \phi E_0 \left[\left(1/\xi - \Delta_t\right) (H_T^0)^{-\xi} N_t^0 - \left(H_T^0 + (1/\xi)(H_T^0)^{-\xi}\right) N_t^0\right]$$

$$= e^{-\left(\lambda_0 - r - \theta^2/\gamma + \lambda\right)t} \phi \left(e^{-\xi (t-T)} C_1 - C_2\right) N_0$$

where $\phi$ and $N^0$ are defined as in the proof of Proposition 1, the second equality follows from the law of iterated expectations, the dynamics of the agent’s health status in equation (51) and the fact that the process $N^0$ is a geometric Brownian motion; and we have set

$$C_1 = \left(1/\xi - \Delta_t\right) (H_T^0)^{-\xi},$$

$$C_2 = H_T^0 + (1/\xi)(H_T^0)^{-\xi}.$$ 

Finally, taking the limit on both sides of the above expression and using the fact that the constants $C_1$ and $C_2$ are finite shows that conditions (17) and (17) are necessary and sufficient for the validity of equation (70).

\[ \Box \]

Proof of Proposition 2. Using standard results on Poisson point processes we have that the life expectancy of a retired agent is given by

$$\ell(W_t, H_t) = E_t[\tau] = E_t \left[ \int_t^\infty e^{-\int_t^s \lambda(H^*_u)du}ds \right]$$

where $H^*$ denotes the path of the agent’s health status under the optimal strategy.

Applying the Feynman-Kac formula we have that the function $E$ solves the partial differential equation

$$\lambda(H)\ell(W, H) = L^*\ell(W, H) + 1$$

(71)
where $L^*$ is the differential operator associated to $(W, H)$ under the optimal strategy. In accordance with the method used in the rest of the paper, we consider an approximation of the form

$$\ell(W, H) = \ell_0(W, H) + \lambda_1 \ell_1(W, H) + o(\lambda_1^2)$$

where $\ell_0(\cdot) = 1/\lambda_0$ is the life expectancy associated with the health independent mortality case and

$$\ell_1(W, H) = \frac{\partial \ell(W, H)}{\partial \lambda_1} \bigg|_{\lambda_1=0}$$

is the first order correction induced by the presence of health dependent mortality. Substituting this approximation into equation (71) and expanding the result in powers of $\lambda_1$ shows that the function $E_1(\cdot)$ is a solution to the partial differential equation

$$\lambda_0 \ell_1 = L^0 \ell_1 - \frac{1}{\lambda_0 H^\xi}$$

where $L^0$ is the differential operator associated to $(W, H)$ under the optimal strategy of the health independent mortality case. Guessing a wealth independent solution of the form $\ell_1(W, H) = \varpi H^{-\xi}$ leads to

$$-\varpi \lambda_0 = \varpi \xi \left( (\alpha B(t))^{\alpha-\delta} - \delta \right) + \frac{1}{\lambda_0}$$

and solving that equation for $\varpi$ gives the desired result. The restriction imposed by equation (45) is a transversality condition which guarantees that the first order correction to the agent’s life expectancy is negative and increasing in the agent’s health status. Its derivation being similar to that of equation (34) we omit the details.

\[\square\]

B Construction of Figure 1

Assume that the agent’s financial wealth, $W$, is nonnegative for otherwise the comparative statics of the health investment share with respect to health are simply reversed. Differentiating equation (38) with respect to the agent’s health status shows that the
optimal health investment share decreases with the agent’s health status if

\[ W \geq G(t, H) = -P(t, H) + \frac{B(t)}{\xi} H + \frac{\alpha B(t)}{\lambda_1 \eta \xi \Delta(t)} H^{1+\xi} \]

and increases otherwise. Similarly, differentiating equation (39) with respect to financial wealth shows that the optimal health investment share decreases with the agent’s financial wealth if and only if \( H \geq H(t) \) where \( H(\cdot) \) is defined implicitly by

\[ \alpha B(t) H(t)^{1+\xi} + \lambda_1 \eta \Delta(t) P(t, H(t)) = 0. \]  \hspace{1cm} (72)

In particular, the portfolio share increases with the health status as long as financial wealth is positive; and increasing in financial wealth if and only if the agent’s future income is insufficient to cover his minimal consumption needs in the sense that \( P(t, H) \leq 0 \) or, equivalently,

\[ H \leq \overline{H}(t) = -C(t)/B(t). \]  \hspace{1cm} (73)

Figure 1 summarizes these results by providing a graphical representation of the comparative statics in the \((W, H)\)-space.

</table>

Notes: Income is divided by 10^6 and health is measured between 1 (Poor) and 5 (Excellent). Results are robust to sampling weights, additional socio-demographic regressors, measurement errors, cohort effects and White’s correction of the variance covariance matrix. Tobit estimations lead to the same conclusions. (standard errors), statistical significance at the 1% level (***), 5% level (**) and at the 10% level (*).

</table>

Notes: Except for the data column all reported values are implied variables at point estimates of structural parameters. \(\ell(H)\) is life expectancy conditional on the agent health level being equal to \(H\). The data column reports expected longevity at age 70 as estimated by (Lubitz et al., 2003, Figure 2, p. 1052). Model implied longevity for various values of \(\xi\) are obtained from Eq. (46).
