July 30, 2010
Abstract

We study the existence of dynamic equilibria with endogenously complete markets in continuous-time, heterogenous agents economies driven by diffusion processes. Our main results show that under appropriate conditions on the transition density of the state variables, market completeness can be deduced from the primitives of the economy. In particular, we prove that a sufficient condition for market completeness is that the volatility of dividends be invertible and provide higher order conditions that apply when this condition fails as is the case in the presence of fixed income securities. In contrast to previous research, our formulation does not require that securities pay terminal dividends and thus allows for both finite and infinite horizon economies.

Keywords: continuous-time asset pricing, dynamic market completeness, general equilibrium theory.

1 Introduction

Ever since the seminal contributions of Kreps (1982), Duffie and Huang (1985) and Duffie (1986) the standard way of constructing securities market equilibria in continuous-time economies with heterogeneous agents has consisted in three steps. First, compute an Arrow-Debreu equilibrium. Second, define candidate prices for the traded risky securities by using the associated consumption price process as a pricing kernel and, third, verify that these prices give rise to dynamically complete markets. The last step in this program is crucial in establishing the existence of an equilibrium. Otherwise we cannot guarantee that the allocation of the Arrow-Debreu equilibrium can be implemented by dynamic trading in the given set of securities. This last step is also the most difficult one since the candidate prices are given by conditional expectations which can rarely be computed explicitly.

In representative agent economies market completeness does not matter for the existence of an equilibrium but it is nonetheless important for two reasons. First, the microeconomic justification for such economies relies on aggregation results which require complete markets, see Constantinides (1982). Second, it is now quite common in asset pricing to start from a representative agent economy and then use the equilibrium pricing kernel “outside the model” to price securities, such as derivatives, that were not included in the original menu of assets. Such an approach requires complete markets since only in that case does the derived price give the amount necessary to replicate the cash flows by trading in the primitive securities.

Despite its importance, the question of endogenous completeness has not received much attention in the general equilibrium literature. In fact, most of the papers that study multi-asset equilibrium models assume in one form or another that markets are complete but do not actually prove it. A notable exception is Anderson and Raimondo (2008) who assume that (i) the economy has a finite horizon and all securities pay dividends at the terminal time, and (ii) the state variables are given by Brownian motions; and prove that the candidate prices generate complete markets as soon as the volatility matrix of the terminal dividends is nondegenerate.

Being the first of its kind, the result of Anderson and Raimondo (2008) is obviously very important. However, their assumptions are often too strong to be applicable in practice. For example, (i) requires that all traded assets pay terminal dividends and hence does not allow for securities that pay only continuous dividends as is customary in the literature. Furthermore, this assumption implies that the menu of traded securities cannot include instantaneously risk free bonds.\footnote{This restriction is not in itself unnatural as one could use a zero coupon bond in zero net supply in place of instantaneously risk free bond and then change numéraire to obtain a truly riskless asset.} Another obvious,
but nonetheless important, limitation of (i) is that it does not allow for infinite horizon economies. While (ii) is satisfied in the benchmark case where dividends are modeled as correlated geometric Brownian motions, Anderson and Raimondo (2008) themselves remark that this assumption is quite restrictive. In particular, this assumption does not allow for mean reversion in the state variables and thus excludes all of the standard equilibrium term structure models that assume mean reverting affine state variables, see e.g. Vasicek (1977) and Cox et al. (1985).

In this paper, we extend the result of Anderson and Raimondo (2008) by removing both of their key assumptions. Specifically, we provide conditions for endogenous completeness in a continuous-time economy populated by heterogenous agents and driven by a multidimensional diffusion process satisfying appropriate regularity conditions. In our formulation, the traded securities do not need to pay terminal dividends. As a result, the horizon of the economy can be either finite or infinite and we can include instantaneously risk free bonds in the menu of traded assets as is customary in the asset pricing literature. In this setting, the main results of this paper show that dynamic market completeness can be deduced from the primitives of the economy in most standard continuous-time equilibrium models.

To highlight the intuition behind our results consider a finite horizon economy and recall that, in continuous-time, market completeness is equivalent to the invertibility of the price volatility. Using a first order expansion we show that this matrix is invertible in neighborhood of the terminal time provided that the exogenous volatility of dividends is invertible and the question becomes that of knowing whether we may propagate this property to the whole time interval. As observed by Anderson and Raimondo (2008), who were the first to use it in this context, the notion of real analyticity is uniquely suited to answer this question because a real analytic function is either identically equal to zero or almost everywhere different from zero. Under our assumptions the determinant of the price volatility is indeed real analytic as a function of time and the state variables, and combining this property with our expansion shows that markets are endogenously complete as soon as the exogenous volatility of dividends is invertible at least at one point of the state space.

The requirement that the volatility of the dividends be nondegenerate is sufficient for endogenous completeness but it is not necessary. In particular, if some of the traded assets are fixed income securities, such as bonds or annuities, then this requirement fails but markets may nonetheless be complete in equilibrium. To obtain sufficient conditions for market completeness in such cases it is necessary to expand the price volatility to higher orders and we provide complete details for the
second order expansion. Since some of the securities now draw their value solely from variations in the pricing kernel, the second order condition that we obtain depends not only on the dividends but also on the agents’ preferences and endowments through the equilibrium pricing kernel and might thus be difficult to apply as the latter can rarely be computed explicitly. To circumvent this difficulty we show that, surprisingly, the validity of the condition for one arbitrary agent in the economy is sufficient to guarantee the existence of equilibrium for a generic set of initial endowments.

In an infinite horizon economy there is no terminal time close to which the volatility of the candidate prices can be approximated. Instead, we expand the volatility of prices as a function of the agents’ common discount rate and show that its determinant can be computed from the primitives of the economy in a neighborhood of infinity. Relying on this expansion we show that an equilibrium exists as soon as the dividend volatility is invertible and provide a second order condition that applies when dividends are degenerate. In contrast to the finite horizon case, the existence result that we obtain holds for generic, rather than fixed, initial endowments and discount rates. The reason for this is that by varying the agents’ discount rate we are changing the initial distribution of wealth in the economy.

The rest of the paper is organized as follows. In Section 2 we present the model, state our assumptions and recall some basic results about Arrow-Debreu equilibria. Section 3 contains our main conditions for endogenous market completeness in finite or infinite horizon economies. In Section 4 we provide examples of models in which our assumptions on the primitives are satisfied. The proofs of our most important results are provided in the appendix. More standard proofs as well as additional results are presented in the online supplement.

2 The economy

Information structure. We consider a continuous-time economy on the time span $[0, T]$ for some horizon $T$ that can be either finite or infinite.

Uncertainty is represented by a probability space $(\Omega, \mathcal{F}, \mathbb{F}, P)$ supporting a Brownian motion $Z \in \mathbb{R}^d$. The filtration $\mathbb{F} = (\mathcal{F}_t)_{t \in [0, T]}$ is the usual augmentation of the filtration generated by the Brownian motion, and we let $\mathcal{F} \equiv \mathcal{F}_T$.

Securities markets. The financial market is frictionless and consists in $1 + d$ continuously traded securities: one locally riskless money market account in zero net supply, and $d$ dividend–paying stocks in positive supply of unit each.
Stock $i$ pays dividends at rate $^2g_i(X_t)$ for some real analytic function $g_i : \mathbb{R}^n \rightarrow \mathbb{R}^+$ where $X_t \in \mathbb{R}^n$ is a state variable that evolves according to

$$X_t = X_0 + \int_0^t \mu_X(\tau, X_\tau) d\tau + \int_0^t \sigma_X(\tau, X_\tau) dZ_\tau$$

for some $X_0 \in \mathbb{R}^n$ and some functions $\mu_X$ and $\sigma_X$ with values in $\mathbb{R}^n$ and $\mathbb{R}^{n \times d}$. The key conditions we impose on the state variables are summarized in:

**Assumption A:**

(a) $n = d$ and $\text{rank}(\sigma_X(t, x)) = d$ for all $(t, x) \in [0, T] \times \mathbb{R}^n$,

(b) The functions $\mu_X, \sigma_X$ are jointly real analytic in $(t, x) \in [0, T] \times \mathbb{R}^n$ and time independent if the economy has an infinite horizon.

(c) The unique solution to equation (1) takes values in $\mathcal{X} \subseteq \mathbb{R}^d$ and admits a transition density $p(t, x, \tau, y)$ that is smooth for $t \neq \tau$.

(d) There are locally bounded functions $(K, L)$, a metric $d$ that is locally equivalent to the Euclidean metric, and constants $\epsilon, \alpha, \phi > 0$ such that $p(t, x, \tau, y)$ is analytic with respect to $t \neq \tau$ in the set

$$\mathcal{D}_\epsilon^2 \equiv \{ (t, \tau) \in \mathbb{C}^2 : \Re \tau \leq T \text{ and } |\Im(\tau - t)| \leq \epsilon \Re(\tau - t) \}$$

and satisfies

$$|p(t, x, \tau, y)| \leq K(x)L(y)|\tau - t|^{-\alpha} e^{\phi|\tau - t| - \frac{d(x, y)^2}{|\tau - t|^2}} \equiv p(t, x, \tau, y)$$

for all $(t, \tau, x, y) \in \mathcal{D}_\epsilon^2 \times \mathcal{D}_\epsilon^2$.

The most important part in the above assumption is condition (d). This condition is meant to guarantee that the candidate equilibrium prices to be constructed below are real analytic functions of time and can be shown to hold in many different models. See Section 4 for various examples.

**Preferences and endowments.** The economy is populated by $A \geq 1$ agents indexed by $a$. The preferences of agent $a$ over lifetime consumption plans are represented by an expected utility index of the form $U_a(c) \equiv E_0 \int_0^T e^{-\rho \tau} u_a(c_\tau) d\tau$ where the constant $\rho \geq 0$ is a discount rate that is common to all agents and $u_a$ is a utility function that is assumed to satisfy the following:

---

2The assumption that the stocks do not pay terminal dividends is adopted for simplicity and can be relaxed at the cost of more involved notation. See the online supplement.
ASSUMPTION B: The function $u_a : (0, \infty) \to \mathbb{R}$ is real analytic, increasing, strictly concave and satisfies the Inada conditions at zero and infinity.

Agent $a$ is endowed with $\eta_{ai} \in [0, 1]$ units of stock $i$ and receives income at rate $\ell_a(X_t)$ for some real analytic function $\ell_a : \mathcal{X} \to \mathbb{R}_+$. We let $\eta \in \mathbb{R}^{A \times d}$ denote the matrix of initial endowments and assume that $\eta^\top 1_A = 1_d$ so that markets clear.

Trading strategies and feasible plans. A trading strategy is a predictable process $(\alpha, \pi) \in \mathbb{R}^{1+d}$ where $\alpha_t$ and $\pi_{it}$ denote the number of units of the riskless asset and the number of units of stock $i$ held in the portfolio at time $t$.

A trading strategy $(\alpha, \pi)$ is said to finance the consumption plan $c$ for agent $a$ at cost $w$ if the associated wealth process $W_t \equiv \alpha_t B_t + \pi_t^\top S_t$ has nonnegative terminal value and satisfies the dynamic budget constraint

$$W_t = w + \int_0^t \alpha_t dB_t + \int_0^t \pi_t^\top (S + D)_t - \int_0^t (c_t - \ell_a(X_t)) d\tau$$

where $D$ and $(B, S)$ denote respectively the vector of cumulative dividends and the endogenous securities price processes.

A plan $c$ is feasible for agent $a$ given a consumption price process $m$ if there exists a trading strategy that finances it at an initial cost of $w_a \equiv \eta_a^\top S_0$ and which is such that $m_t W_t + \int_0^t m_\tau (c_\tau - \ell_a(X_\tau)) d\tau$ is a martingale. The latter requirement is a standard admissibility condition that rules out doubling strategies from the set of allowed trading strategies (see e.g. Duffie (2001, Chapter 6)). In what follows we denote by $\mathcal{C}_a(m, B, S)$ the set of consumption plans that are feasible for agent $a$ given the consumption and securities prices $m$, $B$ and $S$.

Equilibrium. The concept of equilibrium that we use is that of equilibrium of plans, prices and expectations introduced by Radner (1972):

DEFINITION 1: An equilibrium is a set of price processes $(m, B, S)$, a consumption allocation $(c_a)_{a=1}^A$ and a set of strategies $(\alpha_a, \pi_a)_{a=1}^A$ such that

(a) The plan $c_a$ maximizes $U_a$ over $\mathcal{C}_a(m, B, S)$ and is financed by $(\alpha_a, \pi_a)$,

(b) All markets clear.

Markets are said to be dynamically complete if any sufficiently integrable consumption plan can be financed by some strategy at some finite initial cost.

The rest of the paper is devoted to finding conditions under which there exists an equilibrium with dynamically complete markets. The starting point of our analysis
will be a static Arrow-Debreu equilibrium defined as a consumption price process \( m \) and a consumption allocation \((c_a)_{a=1}^A\) such that \(c_a\) maximizes \(U_a\) over the set of consumption plans which satisfy the static budget constraint
\[
E \int_0^T m_\tau \left( c_\tau - \ell_a(X_\tau) - \eta_a^\top g(X_\tau) \right) d\tau \leq 0,
\]
and the consumption good market clears. To guarantee that such an equilibrium exists we impose the following:

**Assumption C:** There are constants \(0 < \gamma_1 \leq \gamma_2, R \leq \rho \) and \(\nu > 1\) such that the relative risk aversion of all agents is bounded between \(\gamma_1\) and \(\gamma_2\) and
\[
\int_0^T \sum_{n=1}^2 \left( \int_{\mathcal{X}} e^{-R\tau} \bar{g}(y)^{1-\gamma_n} \bar{p}(t,x,t+\nu\tau,y) dy \right) d\tau < \infty
\]
for all \((t,x) \in \mathcal{P} \times \mathcal{X}\) where \(\bar{p}\) is defined by equation (2) and \(\bar{g} \equiv g^\top 1_d + \ell^\top 1_A\) denotes the aggregate consumption function.

Our first result establishes the existence of an Arrow–Debreu equilibrium and characterizes the corresponding consumption price process:

**Proposition 1:** The set of Arrow-Debreu equilibria is non empty. In any such equilibrium the consumption price process is given by
\[
m_t = m(t,X_t) \equiv e^{-\rho t} \frac{\partial u}{\partial c} (\lambda, \bar{g}(X_t))
\]
for some \(\lambda \in \mathcal{I}_+\) where \(u(\lambda,c) = \max_{s \in \mathcal{S}} \sum_{a=1}^A \lambda_a u_a(s,c)\) and \(\mathcal{S} \subseteq \mathbb{R}^A\) denotes the unit simplex. In particular, the equilibrium consumption price function is jointly real analytic in \((t,\lambda,x) \in (0,T) \times \mathcal{I}_+ \times \mathcal{X}\).

**Remark 1:** We focus on a formulation with homogenous discount rates and time independent aggregate consumption because it covers most of the cases of interest and allows to guarantee that equilibrium prices are real analytic under simple conditions. While it is possible to find conditions on the primitives of the model under which that property holds with heterogenous discount rates and/or time dependent aggregate consumption these conditions are a lot more involved and become very difficult to interpret. See Appendix B for details.

\footnote{The assumption of bounded risk aversions is needed to insure the generic determinacy of equilibria and is only used in the proofs of Theorems 2 and 3. A less stringent condition that is sufficient for the existence of an Arrow-Debreu equilibrium is provided in the online supplement.}
3  Endogenous completeness

In order to find conditions under which our economy admits an equilibrium with dynamically complete markets, we will follow the path set by Kreps (1982), Duffie and Huang (1985), Duffie (1986) and Huang (1987). Namely, we will start from a given Arrow-Debreu equilibrium, then construct candidate prices for the traded securities by using the consumption price process as a state price deflator and finally check whether these prices deliver complete markets.

3.1 Candidate price functions

Fix an Arrow-Debreu equilibrium and let \( m_t \equiv m(t, X_t) \) denote the corresponding consumption price. Appealing to Proposition 1 for the required smoothness and applying Itô’s lemma shows that

\[
-A_t \equiv \int_0^t E_\tau \left[ \frac{dm_\tau}{m_\tau} \right] = \int_0^t \frac{\mathcal{D}(m(\tau, X_\tau))}{m(\tau, X_\tau)} d\tau,
\]

where the second order differential operator

\[
\mathcal{D} \equiv \frac{\partial}{\partial t} + \mathcal{A} = \frac{\partial}{\partial t} + \mu_X(t, x)^\top \frac{\partial}{\partial x} + \frac{1}{2} \text{Tr} \left[ \sigma_X(t, x)\sigma_X(t, x)^\top \frac{\partial^2}{\partial x^2} \right]
\]

denotes the extended infinitesimal generator of the state variables. Accordingly, we will take \( B_t \equiv \exp(A_t) \) as our candidate for the price of the riskless asset. On the other hand, a natural candidate for the stock price is the fundamental value of dividends computed at the equilibrium consumption price, namely

\[
S_t = S(t, X_t) \equiv E_t \int_t^T m(\tau, X_\tau) \frac{m(t, X_t)}{m(\tau, X_\tau)} g(X_\tau) d\tau.
\]

The following result establishes some properties of the candidate price function that will prove crucial for the existence of an equilibrium.

**Proposition 2:** The function \( S \) is jointly real analytic in \((t, x) \in (0, T) \times \mathcal{X}\) and belongs to \(C^\infty((0, T] \times \mathcal{X})\).

As is well-known, to assert that the candidate prices give rise to an equilibrium it suffices to prove that, given these prices, markets are dynamically complete. In a continuous time model, the latter is closely related to the properties of the stock volatility. Specifically, it can be shown that markets are complete if and only if the stock volatility is almost everywhere invertible (see Duffie (2001, Chapter 6)). Since \( S \) is smooth, an application of Itô’s formula shows that the volatility of the candidate
stock prices is given by \( \sigma_S(t, X_t) = \frac{\partial S}{\partial x}(t, X_t) \sigma_X(t, X_t) \). Combining this with the fact that a real analytic function is either identically zero or almost everywhere different from zero delivers the following:

**Proposition 3:** If \( \text{det}(\sigma_S(t, x)) \neq 0 \) for some \((t, x) \in (0, T) \times \mathcal{X}\) then there exists an equilibrium with dynamically complete markets.

The main obstacle one encounters when trying to apply the above Proposition is that, unless \( d \equiv 1 \) or the candidate price function can be computed in closed form, it is in general very difficult to check that its volatility is invertible even at a single point.\(^4\) To circumvent this difficulty, we show in the next section that it may be sufficient to check that the volatility of the intermediate dividends, rather than that of the candidate prices, is nondegenerate.

### 3.2 Conditions for market completeness

In this section we present conditions that are sufficient to guarantee that the price volatility is invertible and, hence, that there exists an equilibrium with complete markets. To highlight the intuition behind our approach we start by considering the finite horizon case before we turn to infinite horizon economies.

#### 3.2.1 Finite horizon economies

Let \( T \) be a finite horizon, fix an Arrow-Debreu equilibrium and denote by \( S \) the corresponding candidate price function. Using equation (3) in conjunction with Proposition 2 and standard martingale arguments shows that the candidate prices solve the partial differential equation

\[
-\frac{\partial}{\partial t}(m(t, x)S(t, x)) = \mathcal{A}(m(t, x)S(t, x)) + m(t, x)g(x)
\]

subject to \( S(T, x) = 0_d \) where \( \mathcal{A} \) denotes the infinitesimal generator of the state variables. Differentiating with respect to \( x \) on both sides and using the continuity of derivatives established in Proposition 2 then gives

\[
\frac{\partial S}{\partial x}(t, x) = (T - t)g'(x) + o(T - t)
\]

\(^4\)An important case in which this property can be checked quite easily is that of finite horizon economies where all risky securities pay terminal dividends as in Anderson and Raimondo (2008). Indeed, in such case the price volatility coincides with that of the terminal dividends at time \( T \) and it suffices to assume that the latter is nondegenerate to obtain the existence of a complete markets equilibrium. See the online supplement for details.
and it follows that
\[ \sigma_S(t, x) = (T - t)\sigma_g(T, x) + o(T - t) \]
where the matrix valued function \( \sigma_g(t, x) \) denotes the volatility of dividends. This simple expansion shows that the determinant of the price volatility is proportional to the determinant of the dividend volatility in a neighborhood of the terminal time and leads to the following:

**Theorem 1:** If \( \det(\sigma_g(T, x)) \neq 0 \) for at least one \( x \in \mathcal{X} \) then there exists an equilibrium with dynamically complete markets.

The conclusion of Theorem 1 is quite intuitive. Indeed, this result simply states that under our assumptions non degeneracy of the exogenous volatility of dividends is automatically transmitted to the endogenous volatility of the prices and thus ensures market completeness. A striking feature of this result is that it only depends on the dividends: Changing the utility functions, initial endowments and/or labor income has no effect on the existence of an equilibrium.

The condition of Theorem 1 is sufficient for the existence of an equilibrium but it is not necessary. In particular, if some of the traded assets are fixed income securities, then this condition fails but markets may nonetheless be complete as illustrated by Example 1 below. To find sufficient conditions for dynamic market completeness in such cases we perform a second order expansion of the volatility matrix. Differentiating equation (4) with respect to \( (t, x) \) and using the continuity of the derivatives of the candidate prices shows that
\[ \sigma_S(t, x) = (T - t)\sigma_g(T, x) + \frac{1}{2}(T - t)^2H(x) + o(T - t)^2 \]  
(5)

where we have set
\[ H(x) \equiv \frac{\partial}{\partial x} \left( \frac{\mathcal{D}(m(T, x)g(x))}{m(T, x)} \right) \sigma_x(T, x) - 2 \frac{\partial \sigma_g}{\partial t}(T, x). \]  
(6)
Combining this expansion with well-known results on determinants then leads to a second order condition for the existence of an equilibrium with dynamically complete markets. Specifically, defining
\[ B_i(x) = \sigma_g(T, x) + e_i e_i^\top (H(x) - \sigma_g(T, x)) \]
where \( e_i \) is the \( i \)th vector in the orthonormal basis of \( \mathbb{R}^d \), it can be shown that an equilibrium with dynamically complete markets exists provided that \( \det(B_1(x)) + \)
\[ \cdots + \det(B_d(x)) \neq 0 \text{ for some } x \in \mathcal{X}. \]  
In contrast to that of Theorem 1, this condition depends not only on dividends but also on preferences and endowments through the pricing kernel and might thus be difficult to apply since \( m \) can rarely be computed in closed form. We show below that the following striking result holds true: an equilibrium with dynamically complete markets exists for generic initial endowments if we replace the marginal utility of the representative agent in (6) by that of any single agent. We need to consider generic endowments because we further expand the price volatility around the case when the economy is populated by a single agent.

To state the result, let \( m_a(t, x) \equiv e^{-\rho t} u'_a(\bar{g}(x)) \) denote the discounted marginal utility of agent \( a \) evaluated at the aggregate consumption and set

\[ B_{a,i}(x) = \sigma_g(T, x) + e_i e_i^\top (H_a(x) - \sigma_g(T, x)) \]  
where the vector \( e_i \in \mathbb{R}^d \) is defined as before and the function \( H_a \) is defined as in equation (6) but with the function \( m \) replaced by \( m_a \).

**Theorem 2:** If \( \det(B_{a,1}(x)) + \cdots + \det(B_{a,d}(x)) \neq 0 \text{ for some } a \text{ and some } x \in \mathcal{X}, \) then an equilibrium with dynamically complete markets exists for almost every matrix \( \eta \) of initial endowments.

The following example illustrates how one can apply Theorem 2 to establish the existence of a complete markets equilibrium in an economy where Theorem 1 fails due to the fact that one of the traded assets is a fixed income security.

**Example 1:** Consider a finite horizon economy where at least one agent, say agent one, has constant relative risk aversion \( \gamma > 0 \) and let \( d \equiv 2 \). Assume that

\[ dX_{1t} = \left( X_{2t} - \|\sigma_1\|^2/2 \right) dt + \sigma_1^\top dZ_t, \]  
\[ dX_{2t} = \kappa (\theta - X_{2t}) dt + \sigma_2^\top dZ_t, \]  
for some constants \( (\kappa, \theta, \sigma_i) \) such that \( \det(\sigma_1, \sigma_2) \neq 0 \); and that the dividends rates are given by \( g_1(x) \equiv 1 \) and \( g_2(x) \) for some real analytic function \( g_2 \).

Using Proposition 4 in conjunction with well-known results on Gaussian processes we have that Assumptions A, B and C hold. However, Theorem 1 cannot be used to assert the existence of an equilibrium because the dividend volatility is degenerate. To circumvent this difficulty we use Theorem 2. Since agent 1 has power utility a direct calculation shows that

\[ \sum_{i=1}^2 \det(B_{1,i}(x)) = \frac{\gamma g_2'(x) \bar{g}'(x)}{\bar{g}(x)} \det(\sigma_1, \sigma_2) \]
is non zero as soon as $\gamma' \neq 0$ and it follows from Theorem 2 that an equilibrium with dynamically complete markets exists for generic initial endowments.

**Remark 2**: Theorem 1 and 2 show that market completeness can be deduced from the primitives provided that the prices are real analytic functions of time and the state variables. Proposition 2 shows that this is the case under our assumptions but in general this property might be difficult to check and it is therefore natural to wonder whether this technical requirement is crucial. We show in the online supplement that this is indeed the case by providing examples of representative agent economies that fail to admit a complete markets equilibrium despite nondegenerate dividends because the candidate prices are not real analytic.

### 3.2.2 Infinite horizon economies

In an infinite horizon economy there is no terminal time close to which the price volatility can be approximated and, as result, the approach of the previous section cannot be used. Instead we will expand the volatility of the candidate prices as a function of the agents’ common discount rate and use this expansion to derive conditions for the generic existence of a complete markets equilibrium.

Using equation (3) it can be shown that volatility matrix of the candidate prices is real analytic in $\rho$ and satisfies\(^5\)

$$
\sigma_S(x, \rho) = \frac{1}{\rho} \sigma_g(x) + \frac{1}{2\rho^2} H(x) + o(1/\rho)^2
$$

which is the direct analog of equation (5) for the infinite horizon case. Combining this expansion with some generic determinacy arguments then delivers the following counterpart to Theorems 1 and 2:

**Theorem 3**: If either $\det(\sigma_g(x)) \neq 0$ or $\det(B_{a,1}(x)) + \cdots + \det(B_{a,d}(x))$ for some $a$ and some $x \in X$ then an equilibrium with dynamically complete markets exists for almost every pair $(\rho, \eta)$ with $\rho > R$.

**Remark 3**: A close inspection of the proof shows that Theorem 3 remains valid if we only require equation (2) to hold for real, rather than complex, values of the time arguments. The reason for this important simplification is that with an infinite horizon the volatility of the candidate prices is automatically real analytic as a function of $\rho$ and this is all that is needed to deduce the generic existence of an equilibrium with complete markets from primitives of the model. The result of

\(^5\)In the infinite horizon case, the drift and diffusion of the state variables are assumed to be time independent. As a result, the volatility of dividends is also time independent and the expressions in equations (6) and (7) simplify.
Theorem 3 also extends to the case of heterogeneous discount rates, provided that we make appropriate changes in Assumption C.

4 Applications

In this section we provide examples of classes of models that satisfy the conditions of Assumption A.

Vector autoregressive processes. Assume that the vector of state variables follows a continuous-time vector autoregressive process of the form

$$dX_t = (b(t) - A(t)X_t)dt + \sigma_X(t)dZ_t$$

where $Z \in \mathbb{R}^d$ is a Brownian motion and $b \in \mathbb{R}^d$, $A \in \mathbb{R}^{d \times d}$ and $\sigma_X \in \mathbb{R}^{d \times d}$ are real analytic functions. This class of models includes as a special case the model studied by Anderson and Raimondo (2008) where the state variables coincide with the underlying Brownian motions but it is significantly more flexible as it allows for arbitrary mean reverting Gaussian processes.

Proposition 4: If $\text{rank}(\sigma_X(t)) = d$ for all $t \geq 0$ then Assumption A holds provided that the economy has a finite horizon.

Autonomous diffusion processes. Assume that each of the coordinates of the vector of state variables follows an autonomous diffusion process of the form

$$dX_{it} = \mu_i(X_{it})dt + \sigma_i(X_{it})dZ_{it}$$

for some real analytic drift and volatility functions. Let $\mathcal{X}_i \equiv (l_i, r_i)$ with $-\infty \leq l_i < r_i \leq \infty$ denote the state space of the $i$th coordinate and assume that the solution to equation (8) does not reach the boundaries of $\mathcal{X}_i$ in finite time. For this class of models the existence of a transition density follows from well-known results (see e.g. Itô and McKean (1965, 4.11)) and we have:

Proposition 5: Assume that equation (2) holds for real values of $t \neq \tau$. Then Assumption A holds.

Since the bound only needs to hold for real, rather than complex, values of time, it is much easier to check. For example, relying on the above result it can be shown that if the economy has an infinite horizon, then the coefficients are time independent and additional conditions on the eigenvalues of $A$ are required. See the online supplement for details.
that Assumption A holds, provided that each coordinate follows either an arithmetic Brownian motion; or a square root process:

\[ dX_{it} = (\mu_i - \kappa_i X_{it}) \, dt + \xi_i \sqrt{|X_{it}|} \, dZ_{it} \]

for some \( \xi_i^2 < 2\mu_i \); or a constant elasticity of variance process:

\[ dX_{it} = \mu_i X_{it} \, dt + \xi_i |X_{it}|^{\beta_i} \, dZ_{it} \]

for some \( \beta_i \geq 1 \); or a general one dimensional diffusion whose drift and volatility coefficients \( \mu_i \) and \( \sigma_i \equiv 1/\phi'_i \) are such that \( G_i(y) \equiv (\mu_i \phi'_i + \frac{1}{2} \sigma_i^2 \phi''_i) \circ \phi^{-1}_i(y) \) satisfies a linear growth condition (see Quian and Zheng (2004, Theorem 3.2)).

**General diffusion processes.** To obtain a general class of models in which the conditions of Assumption A are satisfied assume that the drift \( \mu_X \) and volatility \( \sigma_X \) are bounded real analytic functions with bounded derivatives and that the volatility is uniformly elliptic in the sense that

\[ \sup_{(t,x) \in (0,T) \times \mathcal{X}} \| \sigma_X(t,x)^\top \xi \|^2 \geq \varepsilon \| \xi \|^2 \]

for all \( \xi \in \mathbb{R}^d \) and some \( \varepsilon > 0 \). Under these assumptions it follows from the general theory of heat kernel bounds that the states variables admit a transition density which satisfies Assumption A.(d). See for example Eidelman (1969, Theorem 8.1), Lunardi (1995, Chapters 3, 5, 6 & 8) and Auscher (1996).

**Analytic semigroups.** Relying on the semigroup approach to diffusion processes, it can be shown that the bound of Assumption A.(d) holds with \( d(x,y) = C \sum_i |x_i - y_i|^{1/2} \) for some \( C > 0 \), provided that the operator \( \mathcal{A} \) generates an analytic semigroup on an appropriate space of functions. Very general sufficient conditions that cover many important cases can be found in Lunardi (1995), Gozzi et al. (2002) and Grigor’yan (1994, 2003, 2006) among others.

**Appendix**

**A. Proofs**

**Proof of Proposition 1.** The existence result follows by a slight modification of the arguments in Malamud (2008) and is reported in the online supplement. The characterization of the consumption price and its real analyticity follow from Huang
The market clearing condition and the real analytic implicit function theorem (see e.g. Krantz and Parks (2002, Section 2.3)).

**Lemma 1:** The transition density \( p(t, x, \tau, y) \) is jointly real analytic in \((t, x)\) for \( \tau \neq t \). Furthermore, for any constant \( \varepsilon > 0 \) and any vector \( k \in \mathbb{N}_+^d \) there exists a locally bounded function \( A(x) = A(x; \varepsilon, |k|) > 0 \) such that:

\[
\left| \frac{\partial^{k_0+|k|} p(t, x, \tau, y)}{\partial t^{k_0} \partial x_1^{k_1} \cdots \partial x_d^{k_d}} \right| \leq A(x) L(y) |\tau - t|^{-\alpha} + |(\alpha + k_0 + |k|) e^{\phi |\tau - t|} - \frac{d(x, y)^2}{\varepsilon (1+\varepsilon)^{|k|}}. \]

for all \( k_0 \in \mathbb{N} \) and \((t, \tau, x, y) \in \mathcal{P}^2 \times \mathcal{X}^2 \) such that \( d(x, y) > \varepsilon \).

**Proof.** Since the transition density is smooth for \( \tau \neq t \), it follows from standard results that it solves the backward Kolmogorov equation

\[
\mathcal{L}(p(t, x, \tau, y)) = \frac{\partial p(t, x, \tau, y)}{\partial t} + \mathcal{A}(p(t, x, \tau, y)) = 0
\]

for \( t \neq \tau \). Combining this property with Eidelman (1969, Theorem 6.2) shows that \( p \) is real analytic in \( x \in \mathcal{X} \) for \( \tau \neq t \). Furthermore, its radius of analyticity is bounded away from zero when \((t, x)\) vary in a compact subset of \([0, \tau) \times \mathcal{X} \), and joint real analyticity now follows from the results of Siciak (1969).

The second part of the statement follows from Assumption A and standard estimates for solutions of parabolic equations. See Davies (1997), Eidelman (1969, p. 23–28) and the online supplement for details.

**Lemma 2:** Let \( m(x) \equiv e^{m(t, x)} \). Then there exists a constant \( C_m > 0 \) such that

\[
0 < m(x) \leq \sum_{a=1}^{A} \lambda_a u_a(g(x)/A) \leq C_m \left( g(x)^{-\gamma_1} + \tilde{g}(x)^{-\gamma_2} \right).
\]

**Proof.** See the online supplement.

**Lemma 3:** The function \( S \) is well-defined and real analytic in \( t \in (0, T) \).

**Proof.** Fix an arbitrary \( t_0 \in (0, T) \). By Proposition 1 and Lemma 2, we know that the function \( m \) is strictly positive and real analytic with respect to \( t \in [0, T] \), so it suffices to prove that for each \( i \) the function

\[
Q_i(z, x) \equiv m(z, x) S_i(z, x) = \int_z^T \int_{\mathcal{X}} p(z, x, \theta, y)m(\theta, y)g_i(y)dyd\theta
\]

See also Eidelman (1969, Theorem 8.1).
is well-defined and analytic in a complex neighborhood \( P_0 \supset t_0 \). Choosing the neighborhood appropriately we may assume that any segment connecting points \( z \in P_0 \) with \( T \) lies in the set \( P_2 \) of Assumption A. Therefore, it follows from Lemma 2 and the second part of Assumption C that the integrand in (9) has an integrable majorant and it follows that \( Q_i \) is well defined in \( P_0 \). Furthermore, the integrand being analytic in \( z \) by Assumption A and Proposition 1 it follows from the Morera theorem (see e.g. Shabat (1992, Theorem 2) and Eidelman (1969, p.223)) that \( Q_i \) is analytic with respect to \( z \in P \) and the proof is complete.

**Proof of Proposition 2.** Let \( \pi_i(t, x, \tau) \equiv E_t[\mathbf{m}(X_\tau)g(X_\tau)] \). By Proposition 1 and Lemma 2, we know that the function \( \mathbf{m} \) is strictly positive and real analytic with respect to \( x \in X \) so it suffices to show that the result holds for the function

\[
Q_i(t, x) \equiv m(t, x)S_i(t, x) = \int_t^T e^{-\rho \tau} \pi_i(t, x, \tau) d\tau.
\]

Fix an \( x \in X \), pick two open sets \( X_1 \subset X_2 \subseteq X \) such that \( x \in X_1 \) and let \( h_i \equiv n \mathbf{m} g_i \) where \( n : X \to [0, 1] \) is a smooth function that is equal to 1 on \( X_1 \) and to zero outside of \( X_2 \). Using this notation we have \( \pi_i = F_i + H_i \) where

\[
F_i(t, x, \tau) \equiv \int_{X_1^c} p(t, x, \tau, y)(\mathbf{m} g_i - h_i)(y) dy,
\]

\[
H_i(t, x, \tau) \equiv \int_{X_2} p(t, x, \tau, y) h_i(y) dy
\]

and \( X_1^c = X \setminus X_1 \). A direct calculation based on Lemmas 1, 2, Assumption C and the fact that \( d(x, y) > \varepsilon \) for some \( \varepsilon > 0 \) and all \( y \in X_1^c \) shows that for every \( k \in \mathbb{N}^d \) there exists an integrable function \( f_{k,x} \) such that

\[
\left| \frac{\partial^k p(t, x, t + \theta, y)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} (\mathbf{m} g_i - h_i)(y) \right| \leq f_{k,x}(\theta, y)
\]

for all \((t, \theta, y) \in [0, T] \times [0, T - t] \times X_1^c \). Therefore, it follows from the dominated convergence theorem that \( F_i \) is smooth in \( x \) and satisfies

\[
\frac{\partial^k F_i(t, x, \tau)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} = \int_{X_1^c} \frac{\partial^k p(t, x, \tau, y)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} (\mathbf{m} g_i - h_i)(y) dy
\]

for all \((t, \tau) \in [0, T] \). On the other hand, since the function \( h_i \) is smooth and compactly supported, it follows from Eidelman (1969, Theorem 5.3) that \( H_i \) is smooth.
with respect to $x$ and satisfies

$$\frac{\partial^k H_i(t, x, \tau)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} = \int_X \frac{\partial^k p(t, x, \tau, y)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} h_i(y) dy,$$

as well as

$$\lim_{t \to T} \int_t^T e^{-\rho \tau} \frac{\partial^k H_i(t, x, \tau)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} d\tau = 0 \quad (13)$$

Adding (11) and (12) shows that $\pi_i$ is smooth with respect to $x$, and it immediately follows that $Q_i$ is smooth with respect to $x$ and satisfies

$$\frac{\partial^k Q_i(t, x)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} = \int_t^T e^{-\rho(\tau-t)} \frac{\partial^k \pi(t, x, \tau)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} d\tau,$$

as well as

$$\lim_{t \to T} \frac{\partial^k Q_i(t, x)}{\partial x_1^{k_1} \cdots \partial x_d^{k_d}} = 0$$

where the limit follows from (13), (10) and the monotone convergence theorem. Since $Q_i$ is real analytic in time by Lemma 3 we know that it is smooth with respect to $t$ and it thus follows from standard that

$$-\frac{\partial Q_i(t, x)}{\partial t} = \mathcal{A}(Q_i(t, x)) + m(t, x) g_i(x). \quad (15)$$

As a result, any mixed derivative of $Q_i$ can be expressed in terms of derivatives with respect to $x$ and it follows that $Q_i \in C^k((0, T] \times \mathcal{X})$. Finally, since the coefficients of (15) are real analytic in $x$ we know from Eidelman (1969, Theorem 6.2) that $Q_i$ is real analytic in $x$ with a radius of analyticity that is uniformly bounded away from zero when $(t, x)$ vary in compact subsets of $(0, T] \times \mathcal{X}$, and joint real analyticity now follows from Lemma 3 and the results of Siciak (1969).

**Proof of Proposition 3.** Well-known results (see e.g. Duffie (2001, Chapters 6 and 10)) show that, under our assumptions, a complete markets equilibrium exists as soon as $\det(\sigma_S(t, x)) \neq 0$ for almost every $(t, x) \in (0, T] \times \mathcal{X}$. Since $S(t, x)$ is real analytic by Proposition 2, it follows from Krantz and Parks (2002, Proposition 2.2.3) and the definition of the determinant that $\det(\sigma_S(t, x))$ is real analytic, and the result now follows from Anderson and Raimondo (2008, Theorem B.3).

**Proof of Theorems 1 and 2.** The validity of (5) follows by differentiating (4) and using the smoothness of $S$, provided by Proposition 2. Furthermore, a direct but
tedious calculation provided in the online supplement shows that

$$\det(\sigma_S(t, x)) = \theta^d \det(\sigma_g(t, x)) + \frac{\theta^{1+d}}{2} \sum_{i=1}^d \det(B_i(x)) + o(\theta)^{1+d} \quad (16)$$

where $\theta = T - t$. Under the assumption of Theorem 1, this shows that the function $\det(\sigma_S(t, x))$ is not identically zero. Since it is real analytic by Proposition 2 and Krantz and Parks (2002, Proposition 2.2.3), it follows from Anderson and Raimondo (2008, Theorem B.3) that $\det(\sigma_S(t, x))$ is almost everywhere non zero on $(0, T) \times \mathcal{X}$. Combining this with Proposition 3 shows that an equilibrium with complete markets exists and completes the proof of Theorem 1.

To prove Theorem 2 we argue as follows: By the real analytic implicit function theorem, we have that $m(t, x, \lambda)$ is real analytic in $(t, x, \lambda) \in [0, T] \times \mathcal{X} \times \mathcal{S}^{++}$ and satisfies $m(t, x, e_\lambda) = m_\lambda(t, x)$. Since the drift and volatility of the state variables are real analytic, this implies that $\det(B_i(x, \lambda))$ is real analytic in $(x, \lambda) \in \mathcal{X} \times \mathcal{S}^{++}$ and satisfies $\det(B_i(x, e_\lambda)) = \det(B_{a,i}(x))$. Combining this with (16) shows that under the assumption of Theorem 2 the function $\det(\sigma_S(t, x, \lambda))$ is almost everywhere non zero on $(0, T) \times \mathcal{X} \times \mathcal{S}^{++}$ and it only remains to prove that generic Pareto weights $\lambda$ correspond to generic initial endowments $\eta$. As we show in the proof of Theorem 3, our assumptions guarantee that the equilibrium is determinate for almost every $\eta$. Therefore, in a small ball $B(\eta')$ around a generic initial endowment $\eta'$ there exists a $C^1$ bijection between $\eta$ and $\lambda$, and the desired result follows.

Consider now an infinite horizon economy and let $S(x, \rho, \lambda)$ denote the candidate prices of the risky assets, seen as functions of the state variables, the agents’ common discount rate and the Pareto weights.

**Lemma 4:** Under the assumptions of Theorem 3 we have

$$0 = \lim_{\rho \to \infty} \left( \rho \frac{\partial S}{\partial x}(x, \rho, \lambda) - g'(x) \right) = \lim_{\rho \to \infty} \left( \rho^2 \frac{\partial S}{\partial x}(x, \rho, \lambda) - \rho g'(x) - H(x) \right).$$

**Proof.** Since the coefficient of the state variables are time independent we have that $\pi_i(t, x, t+\theta) = \bar{\pi}_i(x, \theta)$ depends only on $(x, \theta)$. It follows from the proof of Proposition 2 that $\bar{\pi}_i \in C^\infty(\mathcal{X} \times [0, \infty))$. Standard martingale arguments imply that that $\bar{\pi}_i$ is a solution to $(\partial/\partial \theta)\bar{\pi}_i = \mathcal{A}(\bar{\pi}_i)$ with the initial condition $\bar{\pi}_i(x, 0) = m(x)g_i(x)$, and the desired result now follows from Lemma 5 below, the definition of the candidate price function and (14).
Lemma 5: If $f \in C^\ell(\mathbb{R}_+)$ is a function such that $e^{-\rho t}f(t)$ is integrable for all $k \leq \ell$ and some $\rho > 0$ then we have

$$\lim_{\rho \to \infty} \rho^k \left( \rho \int_0^\infty e^{-\rho t} f(t) dt - \sum_{i=0}^{k} \rho^{-i} f^{(i)}(0) \right) = 0, \quad k \leq \ell - 1.$$ 

Proof. This proof follows from a standard induction argument based on the dominated convergence theorem and is presented in the online supplement. ■

Lemma 6: Under the assumptions of Theorem 3 and for almost every vector of Pareto weights $\lambda \in \mathcal{S}_{++}$, we have that the candidate prices volatility matrix is almost surely non-degenerate for almost every $\rho > R$.

Proof. Combining the result of Lemma 5 with an argument similar to that we used in the proof of Theorems 1 and 2 shows that

$$\det(\sigma_S(x, \rho, \lambda)) = \frac{1}{\rho^d} \det(\sigma_g(x)) + \frac{1}{2\rho^{1+d}} \sum_{i=1}^{d} \det(B_i(x, \lambda)) + o(1/\rho)^{1+d}.$$ 

Since $S$ is automatically real analytic in $\rho > R$, we have that $\det(\sigma_P(x, \rho, \lambda))$ is also real analytic in $\rho > R$. It follows that the required assertion holds for those $\lambda \in \mathcal{S}_{++}$, for which $|\det(\sigma_g(x))| + (\det(B_i(x, \lambda)) + \cdots + \det(B_d(x, \lambda)) | is not identically equal to zero. Since $\det(B_i(x, e_a)) = \det(B_{a,i}(x))$ and the function $\det(B_i(x, \lambda))$ is real analytic in $(x, \lambda)$, the assumption of the statement guarantees that this holds for generic $\lambda \in \mathcal{S}_{++}$ and the proof is complete. ■

Proof of Theorem 3. Fix the initial endowments for all but the first stock and consider the vector valued mapping defined by

$$G_a(\rho, \lambda) \equiv E \int_0^\infty \frac{e^{-\rho t}m(X_t, \lambda)}{S_1(x, \rho, \lambda)} \left( I_a(\lambda^{-1}m(X_t, \lambda)) - \ell_a(X_t) - \sum_{i>1} \eta_{ai}g_i(X_t) \right),$$ 

where $I_a$ denotes the inverse marginal utility of agent $a$. With this notation we have that the Negishi equation that allows to determine the equilibrium Pareto weights from the agents’ initial endowments is

$$G(\rho, \lambda) = (\eta_{11}, \ldots, \eta_{A1})^\top \equiv \eta_1 \in \mathcal{S}.$$ 

By the existence part of Proposition 1 we know that $G$ is onto. Since, the relative risk aversions are bounded from above and away from zero, it can be shown (see the online supplement for details) using Assumption C and Lemma 2 that $G$ is $C^1$ with
respect to \((\rho, \lambda) \in (R, \infty) \times \mathcal{S}_{++}\). Therefore, by Sard’s theorem (see e.g. Sternberg (1964, Theorem II.3.1)) we get that for each fixed \(\rho > R\) almost every \(\eta_1 \in \mathcal{S}\) is regular for \(G\) in the sense that any solution \(\lambda\) to equation \((17)\) satisfies
\[
\det \left( \frac{\partial G(\rho, \lambda)}{\partial \lambda} \right) \neq 0.
\]

Fix such a regular \((\rho, \eta_1^*)\), let \(\lambda^*\) be a solution to \((17)\) and \(\mathcal{B}\) be a small open neighborhood of \((\rho, \lambda^*)\) such that the mapping \((\rho, \lambda) \rightarrow (\rho, G(\rho, \lambda))\) is \(C^1\) bijection from \(\mathcal{B}\) to some \(\mathcal{B}'\). By Lemma 6, the candidate prices volatility matrix is non-degenerate for almost every \((\rho, \lambda) \in \mathcal{B}\) and the standard change of variable formula implies that the image of such \((\rho, \lambda)\) has full measure in \(\mathcal{B}'\). As a result, a complete markets equilibrium exists for all \((\rho, \eta_1)\) in this image and the desired conclusion now follows from the arbitrariness of the endowments in stocks 2, \ldots, \(d\).

\[\blacksquare\]

**Proof of Propositions 4 and 5.** See the online supplement. \[\blacksquare\]

**B. Alternative assumptions: Time-dependent consumption and heterogenous discount rates**

In this appendix we provide conditions on the dividends, labor income rates and preferences that allow to extend the validity of our finite horizon results to cases in which the aggregate consumption \(g(t, x) = \sum_i g_i(t, x) + \sum_a \ell_a(t, x)\) is time dependent and the discount rates can be heterogenous across agents. The main difficulty in dealing with such cases is that, in order to define the candidate price
\[
S_i(t, x) = \int_t^T \int_{\mathcal{X}} p(t, x, \tau, y) m(\tau, y) g_i(\tau, y) dy
\]
for complex values of \(t\) we need that the radius of complex analyticity of the integrand \(p(t, x, \tau, y) m(\tau, y) g_i(\tau, y)\) be bounded away from zero *uniformly in \(y\).* When discount rates are homogeneous and dividends are time-independent, this is not a problem, as in this case \(m(\tau, y) = e^{-\rho \tau} m(y)\) for some time independent function \(m\). Otherwise, showing the uniform analyticity of \(m\) becomes a highly non-trivial problem that can only be solved under the following stringent conditions:

**Assumption D:** Consider a finite horizon economy and assume that

(a) For any \(\varepsilon > 0\) there exists a complex neighborhood \(\mathcal{O} \supset [0, T]\) such that \(g(t, x)\) can be analytically continued to \(\mathcal{O}\),

\[
|\Im(g(t, x))| \leq \varepsilon \Re(g(t, x)), \quad \text{and} \quad K^{-1} \Re(g(t, x)) \leq \Re(g(t, x)) \leq K \Re(g(t, x))
\]
for all \((t, x) \in \mathcal{O} \times \mathcal{X}\) and some constant \(K = K(\varepsilon, \mathcal{O}) > 0\).

(b) There exists a constant \(\varepsilon > 0\) such that the inverse marginal utilities \(I_a(z)\) are analytic in the sector \(\{z \in \mathbb{C} : |\Im z| < \varepsilon \Re z\}\) and

\[
\lim_{z \in \mathbb{C}, |z| \to \infty} \left( z^{b^\infty_a} I_a(z) - c^\infty_a \right) = \lim_{z \in \mathbb{C}, |z| \to 0} \left( z^{b^0_a} I_a(z) - c^0_a \right) = 0
\]

for each \(a \leq A\) and some constants \(b^0_a, b^\infty_a > 0\) and \(c^0_a, c^\infty_a > 0\).

(c) There exists a constant \(\nu > 1\) such that

\[
\sum_{a=1}^A \int_0^T \int_X e^{-\nu \varepsilon \tau} u'_a(\mathcal{g}(\tau, x)/A) \mathcal{g}(\tau, x) \overline{p}(0, x, \nu \tau, y) dy d\tau < \infty.
\]

where the function \(\overline{p}\) is defined as Assumption A.

Remark 4: A simple case in which condition (a) holds is that where the dividends and labor income rates are given by \(g_i(t, x) = e^{\delta t} g_i(x)\) and \(\ell_a(t, x) = e^{\kappa t} \ell_a(x)\) for some real analytic functions \(g_i, \ell_a \geq 0\). Condition (b) requires that utility functions behave like power functions close to zero and infinity and can be shown to hold for most of the standard utility functions.

The following theorem shows that our results remain valid in this more general setting and concludes this appendix.

Theorem 4: Assume that the aggregate consumption is time dependent and that the agents’ discount rate are heterogenous. Then Propositions 1, 2, 3 and Theorems 1, 2 remain valid, provided that Assumption C is replaced by D.

Proof. See the online supplement. ■
